Acknowledgments

First and foremost, I would like to express my gratitude to my research advisor, Prof. Prakash Ishwar, and my co-advisor, Prof. Janusz Konrad for their support and guidance. During my PhD study, they offered me a lot of help in shaping my research problem and identifying key questions, designing experiments to support a conclusion, finding interesting directions to move my research forward, preparing for oral and poster presentations, and establishing good habits to keep things organized. Also, I would like to thank for their enormous time and effort devoted to revising and organizing drafts of my papers, presentation slides and posters. I especially appreciate Prof. Ishwar for his valuable insights, patience and care for my personal growth and career development. It has been really fortunate to work with them. I would also like to thank other members of my committee, Prof. Vivek Goyal and Prof. Thomas Little, for their valued feedback and suggestions.

Apart from my committee members, I would also like to express my thanks to my collaborator, Natalia Frumkin. She spent a huge amount of time in configuring and debugging our physical testbed, assisting me with all the testbed experiments, and coordinating with the ECE Senior Design team *ActiLocate*. My thanks also go to members of team *ActiLocate* – William Chen, Hannah Gibson, Tu Timmy Hoang, Dong Hyun Kim and Adam Surette – for delivering a functional testbed that met our design requirements.

I would also like to acknowledge some of the current and former members of BU College of Engineering who made my life in Boston more enjoyable: Jiawei Chen, Christy Lin, Rui Chen, Ruidi Chen, Tingting Xu, Henghui Zhu, Dr. Nan Zhou, Ozan Tezcan, Kubra Cilingir, Dr. Jonathan Wu and Xizhi Wu. Their generous help, support and encouragement made me feel at home.

Finally, a special thanks go to my parents and family for their love and support.

They encouraged and helped me in going through the hard times in my life, and without them I would not have achieved what I have today.

This work was supported by the NSF under ERC Cooperative Agreement No. EEC-0812056 and Boston University's Undergraduate Research Opportunities Program. Any opinions, findings, and conclusions or recommendations expressed are those of the author(s) and do not necessarily reflect the views of the sponsors.

ABSTRACT

Indoor occupant localization is a key component of location-based smart-space applications. Such applications are expected to save energy and provide productivity gains and health benefits. Many traditional camera-based indoor localization systems use visual information to detect and analyze the states of room occupants. These systems, however, may not be acceptable in privacy-sensitive scenarios since high-resolution images may reveal room and occupant details to eavesdroppers. To address visual privacy concerns, approaches have been developed using extremely-low-resolution light sensors, which provide limited visual information and preserve privacy even if hacked. These systems preserve visual privacy and are reasonably accurate, but they fail in the presence of noise and ambient light changes.

This dissertation focuses on two-dimensional localization of an occupant on the floor plane, where three goals are considered in the development of an indoor localiza-

tion system: accuracy, robustness and visual privacy preservation. Unlike techniques that preserve user privacy by degrading full-resolution data, this dissertation focuses on an array of single-pixel light sensors. Furthermore, to make the system robust to noise, ambient light changes and sensor failures, the scene is actively illuminated by modulating an array of LED light sources, which allows algorithms to use light transported from sources to sensors (described as light transport matrix) instead of raw sensor readings. Finally, to assure accurate localization, both principled model-based algorithms and learning-based approaches via active scene illumination are proposed.

In the proposed model-based algorithm, the appearance of an object is modeled as a change in floor reflectivity in some area. A ridge regression algorithm is developed to estimate the change of floor reflectivity from change in the light transport matrix caused by appearance of the object. The region of largest reflectivity change identifies object location. Experimental validation demonstrates that the proposed algorithm can accurately localize both flat objects and human occupants, and is robust to noise, illumination changes and sensor failures. In addition, a sensor design using aperture grids is proposed which further improves localization accuracy. As for learning-based approaches, this dissertation proposes a convolutional neural network, which reshapes the input light transport matrix to take advantage of spatial correlations between sensors. As a result, the proposed network can accurately localize human occupants in both simulations and the real testbed with a small number of training samples. Moreover, unlike model-based approaches, the proposed network does not require modeling assumptions or knowledge of room, sources and sensors.

Chapter 1

Introduction

1.1 Background

In the future, smart spaces, which can react to occupants' needs, will likely become a common occurrence in our lifetimes. With advanced sensors, processors and state-of-the-art algorithms, smart spaces are expected to bring a lot of benefits to occupants. For example, they can help save energy by automatically changing lighting and HVAC operation based on occupants' locations, improve people's productivity by allowing location- or gesture-based controls of room facilities, or bring health benefits by providing task-optimized lighting. An illustration of a smart space is shown in Fig. 1-1. However, in order to provide such benefits, the system first needs to understand what room occupants are doing. Therefore, indoor occupant activity analysis, a set of techniques developed to detect and analyze occupant states, is essential. Among these techniques, indoor localization is an important first step to a lot of location-based smart space applications and other activity analysis tasks (e.g., pose estimation and action recognition), and is the focus of this dissertation.

Indoor localization systems can be classified into wearable-beacon-based systems and beaconless systems. Wearable-beacon-based localization approaches require occupants to carry custom-designed electronic devices, such as tags, wearable sensors or a receiver. Many of these systems have deployed anchors that talk to the beacon(s) so that the location of the beacon(s) relative to the anchors can be calculated. These systems are intrusive since the occupants must carry the devices all the time,

Figure 1.1: Illustration of a smart space.

and their performance can be affected by device placement. Beaconless systems, on the other hand, analyze activities without using a wearable device. Instead, they exploit signals that are affected by human activity. Beaconless systems can be classified into passive and active “illumination” systems. Passive “illumination” systems only measure changes in received environmental signals due to human presence or activity. They do not generate signals to be measured, and therefore they are more sensitive to environmental conditions such as noise, multi-path, reflections and interfering objects. Some of them also require re-calibration for each usage-scenario. Active “illumination” systems generate modulated signals, and measure changes in modulated signals reflected by occupants, which indicate human presence or activity. These systems are more robust to environmental conditions since they do not rely on ambient signals.

Vision-based localization systems have become one of the most popular types of passive systems for their high accuracy and reliability. Many indoor localization systems have been proposed using images or videos captured by single or multiple cameras. Although they provide accurate results, they are not suitable for venues

where privacy is expected, such as a bedroom or a bathroom, since videos can reveal details about occupants, their activities and the room itself.

Therefore, methods have been developed to address visual privacy concerns when using images or videos. A popular approach is data degradation after images are captured by cameras. It aims to cover, replace or transform sensitive parts of camera images. While this approach changes or removes the identities of users in images, it is vulnerable to hacking since images are manipulated after capture. Some other approaches preserve privacy by changing the optics of the camera before images are captured, which is more robust to hacking. Besides these, another common approach is to use extremely-low-resolution (eLR) cameras with few pixels¹. These cameras capture very limited user identity information that is useless to eavesdroppers even if hacked.

eLR cameras have been successfully used in indoor localization, both in passive and active illumination systems. Passive illumination systems collect light using an array of eLR cameras with no control over light sources. These methods rely on raw sensor readings and their performance is expected to be highly sensitive to ambient light fluctuations. Active illumination systems, on the other hand, consist of both eLR cameras and modulated light sources. They create an illumination-invariant representation that has information about room state and therefore are robust to ambient lighting changes.

In this dissertation, we will address three main goals when designing an indoor localization system: 1) Accuracy - we want the system to provide accurate estimates of the occupant's location, i.e. minimize the localization error; 2) Robustness - our system should perform consistently well under real-world non-idealities such as environmental noise and illumination changes; 3) Privacy preservation - the definition of

¹With few pixels, the eLR cameras have an extremely low spatial resolution, but each pixel still measures light intensity with high precision.

privacy is subjective and there are different types of privacy. In this dissertation, we only consider visual privacy preservation, which we define as the system’s ability to hide from eavesdroppers the visual appearance of room occupants, so that eavesdroppers are unable to visually (using eyes) identify the occupants from data intercepted from the system (e.g., sensor readings). Visual privacy only serves as a motivation for us to choose the right kind of sensors. We do not seek to quantify how much visual privacy is preserved by our system; we only explored the possibilities.

1.2 Related work

With the development of new, advanced sensors, indoor localization is closer to reality than ever before. Unlike GPS (Misra and Enge, 1999) for outdoor localization, there is no dominant way of localization in an indoor space. Indoor localization systems can be broadly classified into wearable-beacon-based and beaconless systems, based on whether they require carry-on electronic devices on users. Beaconless systems can be divided into passive “illumination” systems that rely on ambient signal measurements, and active “illumination” systems that generate and measure modulated signals. An overview of common indoor localization systems is shown in Fig. 1.2.

1.2.1 Wearable-beacon-based systems

Many early-stage indoor localization systems have been developed using a wearable beacon and a set of fixed anchors. Some systems (Hightower et al., 2000; Priyantha et al., 2000; Ni et al., 2004) use fixed radio-frequency (RF) signal transmitters and an RF signal receiver (e.g., RFID badge) attached to the occupant. The active badge system (Want et al., 1992), on the contrary, uses a wearable transmitter emitting infrared signals and fixed listeners as anchors. These systems estimate the location of the wearable beacon based on the relative signal strengths between the beacon and the anchors. Some more recent wearable-beacon-based systems (Vongkulbhisal

Figure 1-2: Overview of common indoor localization systems.

et al., 2012; Kim et al., 2013; Yang et al., 2014; Zhang et al., 2014; Nadeem et al., 2015; De Lausnay et al., 2015; Steendam, 2018) have been developed using modulated visible light sources and a receiver that can detect the strength, time difference or angle of arrival of received light. These systems are generally more accurate than early-stage systems as the receiver can retrieve more information.

1.2.2 Beaconless systems

Beaconless localization systems are drawing more interest as they are less intrusive to users. Systems based on passive “illumination” have only receivers that measure signals affected by occupants’ activities, including airflow disruption (Krumm, 2016), thermal infrared rays (Hauschildt and Kirchhof, 2010) and audible sound (Mandal et al., 2005; Huang et al., 2016). Location is inferred from the relative strengths of signals received by all sensors. Vision-based localization systems (Brumitt et al., 2000; Zajdel and Kröse, 2005; Petrushin et al., 2006; Wang and Wang, 2007; Munoz-Salinas et al., 2009; Kohoutek et al., 2010) using cameras to capture the scene are also a special kind of passive “illumination” systems, which are accurate but can

bring privacy concerns. Active “illumination” systems, on the other hand, use an extra array of signal transmitters in addition to the receivers. Examples include systems based on WLAN signals (Youssef et al., 2007; Kosba et al., 2009; Moussa and Youssef, 2009), ultra-wideband (UWB) radio signals (Frazier, 1996; Ma et al., 2006; Wilson and Patwari, 2009) and ultrasound (Reijniers and Peremans, 2007; Wan and Paul, 2010). The transmitted signals are highly controlled so that the algorithms can accurately infer occupants’ locations from changes of received signals. These systems are robust to environmental conditions and do not violate privacy, but they are generally not as accurate as vision-based systems.

1.2.3 Visual privacy preservation

To address privacy concerns in vision-based systems, many data degradation methods have been developed. Reversible methods, such as scrambling (Zeng and Lei, 2003; Martínez-Ponte et al., 2005; Senior et al., 2005; Dufaux and Ebrahimi, 2006; Kuroiwa et al., 2007; Dufaux and Ebrahimi, 2008; Ye, 2010; Dufaux, 2011) and encryption (Sadeghi et al., 2009; Gilad-Bachrach et al., 2016; Ziad et al., 2016; Wang et al., 2017), allow exact image recovery. However, scrambling methods can be vulnerable to certain attacks (Macq and Quisquater, 1995). Encryption methods are more secure, but they generally prevent the use of methods based on spatial correlation in images. Irreversible methods, which do not allow exact recovery, can be classified into post-capture and pre-capture methods. Post-capture methods, such as image cartooning (Erdélyi et al., 2013; Erdélyi et al., 2014; Hassan et al., 2017), obfuscation (Boyle et al., 2000; Neustaedter and Greenberg, 2003; Neustaedter et al., 2006; Zhang et al., 2006; Frome et al., 2009; Raval et al., 2017) and human de-identification (Gross et al., 2005; Newton et al., 2005; Gross et al., 2006; Bitouk et al., 2008; Brkic et al., 2017), manipulate images after they have been captured by cameras. Pre-capture methods preserve privacy by either changing the optics of the camera before images

are captured (Pittaluga and Koppal, 2015), or using eLR cameras with an extremely low spatial resolution (Jia and Radke, 2014; Wang et al., 2014; Dai et al., 2015; Chen et al., 2016; Roeper et al., 2016; Wang et al., 2016; Ryoo et al., 2017).

Different types of eLR cameras have been used in indoor localization, tracking and activity analysis systems. Passive illumination systems with eLR cameras include indoor occupant localization using an array of single-pixel color sensors (Roeper et al., 2016), activity recognition using multiple low-resolution cameras (Dai et al., 2015) and head pose estimation using a single monocular low-resolution camera (Chen et al., 2016). Active illumination systems consist of both eLR cameras and modulated light sources. Jia and Radke (Jia and Radke, 2014) developed an occupant tracking and coarse pose estimation system using an array of single-pixel time-of-flight sensors that provide a low-resolution depth map of the room. Wang *et al.* (Wang et al., 2014) and Li *et al.* (Li et al., 2016) proposed two systems for 3D human reconstruction by analyzing blocked rays from light sources to sensors. Wang *et al.* also proposed course-grained room occupancy estimation by analyzing changes in the amount of modulated light reflected by the floor caused by object presence. Among all types of eLR cameras, single-pixel color sensors are usually completely diffuse rather than focused (using a lens), as they only output the aggregated luminous flux intensity inside a wide field of view, which does not require a lens.

1.3 Contributions

The contribution of this dissertation consists of three parts: system framework, localization methods and experimental validations. We developed our indoor localization system *via* active illumination using modulated light sources and single-pixel sensors measuring responses; we also studied two kinds of sensors – classical single-pixel sensors with a wide field of view, and advanced sensors using aperture grids.

For localization methods, we explored both model-based and data-driven methods; we developed model-based algorithms *via* both passive and active illumination, and a data-driven approach based on a convolutional neural network (CNN). For experimental validations, we evaluated our algorithms’ performance *via* both idealized simulations and real-world testbeds, in terms of localization error (accuracy) and robustness. An overview of the contributions is shown in Fig. 1-3.

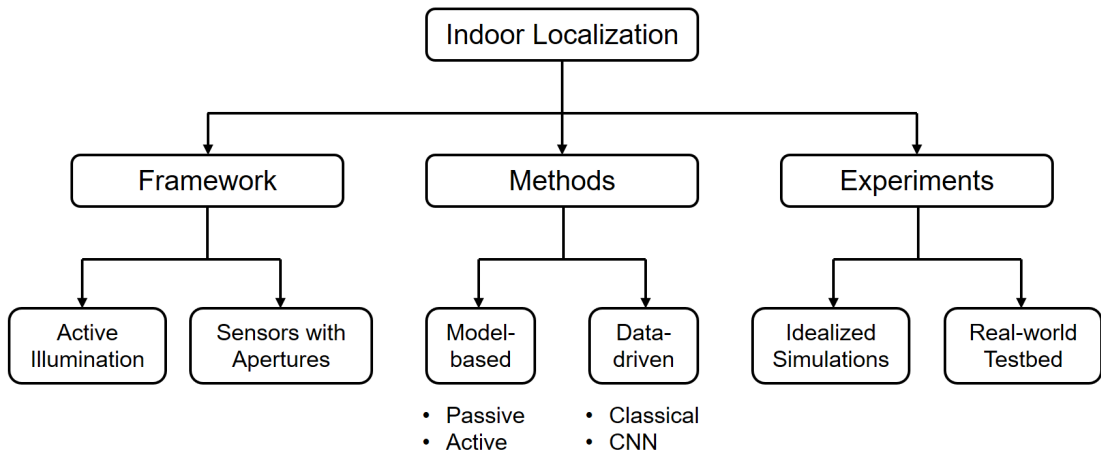

Figure 1-3: Overview of the contributions of this dissertation.

Our proposed methods focus on localization of the change between two room states, no matter what the change results from. We do not focus on localizing a particular type of object, nor do we classify the category of the localized object. Therefore, we assume that all the background objects (e.g., furniture) remain in the same position during localization. Also, we assume that the change of room state is caused by a single, connected object (except Section 3.6.3 where we discuss the case of multiple objects), and the goal of our localization system is to estimate the two-dimensional location of the object centroid on the floor, rather than in the three-dimensional space.

Our system leverages existing LED light sources that are already used to provide lighting for the smart space, so that there is no additional hardware deployment except

the sensors. The LEDs emit broadband light covering the full visible spectrum, which is natural for indoor lighting. We do not include any use of wavelength selectivity.

We only consider office-sized rooms, that is at most $4\text{m}\times 4\text{m}$. We do not consider larger indoor spaces such as large classrooms or conference halls, although theoretically our localization algorithms should work in these scenarios.

1.3.1 System framework

In this dissertation, we developed an indoor occupant localization system where we considered the three goals mentioned above: accuracy, robustness and visual privacy preservation. Unlike techniques that preserve user privacy by degrading full-resolution data, this dissertation focuses on an array of single-pixel light sensors which record very limited visual information, useless to eavesdroppers. Furthermore, to make the system robust to ambient light changes and noise, we leveraged the system architecture for occupancy estimation proposed by Wang *et al.* (Wang et al., 2014) that uses an array of light sources and sensors placed on the ceiling and pointed downward. In this system, the scene is actively illuminated by modulating an array of LED light sources while the sensors measure reflected light. In the context of this dissertation, “modulation” refers to varying the intensities (emission rates) of the LEDs slowly enough such that sensors can obtain steady-state measurements of reflected luminous fluxes. This allows algorithms to use light transport information (between light sources and sensors) instead of raw sensor readings. Finally, to assure accurate localization, we developed principled computational algorithms based on the light reflection model developed by Wang *et al.* and a data-driven approach based on a convolutional neural network (CNN). We compared the performance of both model-based and data-driven approaches in simulated and real-world experiments. Besides, we explored a sensor design using programmable aperture grids to separate incoming light from different directions, which extracts more information from a sensor and

further improves the localization accuracy in simulated experiments.

1.3.2 Model-based localization approaches

In developing our localization algorithms, we consider two types of room illumination: passive and active. A passive illumination system collects data from the scene under fixed light emitted by all light sources. The system has no control over light sources. By contrast, an active illumination system can modulate each light source at a desired frequency while simultaneously collecting data from the sensors. By analyzing the light transported from each source to each sensor we can estimate an object’s location on the floor due to floor albedo change caused by object presence or motion. For each illumination scenario, we proposed a model-based algorithm to localize a single object. Both of our algorithms localize the change between the current state (e.g., room occupied by an object) and an initial state (e.g., empty room) and therefore require one set of measurements for each state.

Both algorithms are derived under several modeling assumptions on which the light reflection model was built (Wang et al., 2014), including Lambertian floor surface, flat objects and ignoring the reflections from walls or furniture. In the passive illumination algorithm, we infer the location of an object from the ratios of sensor reading changes between empty and occupied room states, assuming that the reading changes are solely the result of object presence. In the active illumination algorithm, we use the light transport matrix (indicating the relative amount of light flow between each source-sensor pair) to represent the room state. Then, we estimate the changes of floor reflectivity based on the change in the light transport matrix between the two states. The region of largest reflectivity change identifies the object location.

We evaluated the two algorithms in terms of accuracy and robustness to noise and illumination changes. We will demonstrate experimental results and discuss the algorithms’ strengths and weaknesses in Section 3.4.

1.3.3 Data-driven localization approaches

Besides principled model-based localization approaches, we also considered data-driven approaches which involve training a machine learning model with a collected dataset and testing it on new (unseen) samples. The advantages of data-driven approaches are twofold: first, they do not require the knowledge of room geometry (length, width, height), locations of light sources and sensors, and their detailed characteristics (e.g., the angle distribution of light intensities of a light source); second, unlike model-based approaches, they do not require any modeling assumptions *vis-à-vis* surface properties (e.g., Lambertian floor) and object characteristics (e.g., size, height and shape), and therefore have higher tolerance to real-world non-idealities than model-based approaches. However, a trade-off of data-driven approaches is that they need training data that can best represent different testing scenarios, which is often expensive to collect in a real-world testbed.

In this dissertation, we investigated data-driven localization approaches *via* active illumination, using both classical machine learning models and neural networks. In classical models, like support vector regression (SVR) and k -nearest neighbors regression, a flattened light transport matrix is used as the input. Two regression models are trained to estimate the object location in x - y coordinates. In the neural network approach, we rearranged the entries of a light transport matrix into a 3D input tensor in order to make use of the spatial correlations between sensors. A trained CNN takes the tensor as input and outputs the estimated location (\hat{x}, \hat{y}) .

We will demonstrate the results of different data-driven approaches and compare them with model-based approaches in Section 4.3.

1.3.4 Experimental Validation

We validated both types of localization approaches *via* experiments in computer simulations and real testbeds. In computer-simulated experiments we used **MATLAB** and Unity3D. **MATLAB** is used for most idealized simulations, where the sensor readings and noise are directly calculated using mathematical equations. Unity3D is a video game development engine and is used for more complex scenarios. It captures real-world illumination more accurately than a **MATLAB** model, and is capable of handling objects with complicated surface properties, such as human-shaped avatars and furniture.

To test our localization algorithms in a real-world environment, we have built a small-scale proof-of-concept testbed with 9 LED-sensor pairs and used a piece of cardboard paper as the object. Using this testbed, we provided the first quantitative real-world validation of indoor localization *via* passive and active illumination. Ours is also the first work to demonstrate (*via* both simulations and testbed) that the active illumination approach is quantitatively more accurate and robust to noise and ambient illumination variations than the passive illumination one. Although the testbed is quite idealized, it is a necessary first step before developing a room-scale testbed.

Encouraged by our initial success on the small-scale testbed, we have built another testbed at a real room’s scale. The room-scale testbed is capable of recording data with real human occupants and it can capture more real-world non-idealities resulting from sunlight, furniture, indirect light, etc. We validated our model-based active illumination algorithm and data-driven approaches with the new testbed, and demonstrated that our proposed CNN has the best accuracy overall.

1.3.5 Other findings

Besides development and experimental validation of model-based and data-driven localization approaches, we also expanded our work in the following directions:

1. We extended our model-based active illumination algorithm to 3D, moving and multiple object scenarios. Our initially-proposed algorithm only applies to single, flat (negligible height) and static object due to model assumptions. Therefore, we modified this algorithm so that it can handle 3D, moving and multiple objects.
2. We proposed and compared several localization approaches without measuring the locations of light sources and sensors, that are normally needed by our active illumination algorithm to calculate the light contribution matrix C . We demonstrated that the C matrix can be estimated when we know light transport matrices corresponding to a flat object placed at a few locations on the floor.

1.4 Organization

This dissertation is organized as follows. In Chapter 2, we introduce our model-based indoor localization algorithm *via* passive scene illumination using single-pixel light sensors. In Chapter 3, we introduce our model-based algorithm *via* active scene illumination and demonstrate its accuracy and robustness *via* simulations and testbed experiments. In Chapter 4, we explore several data-driven approaches to localization *via* active scene illumination including a convolutional neural network. In Chapter 5, we summarize the dissertation and point out directions for future work.

Chapter 2

Model-based indoor localization *via* passive scene illumination

2.1 Light reflection model

We briefly introduce the light reflection model, which forms the basis of our localization algorithms. Given the properties of light sources and light sensors in a room, this model relates sensor readings to the reflection properties of surfaces (see Fig. 2.1).

Figure 2.1: The light reflection model.

The model is derived under the following assumptions:

1. The light sources and light sensors are mounted on the ceiling and face downwards; their areas are negligible compared to the area of the ceiling.
2. The light reflected by the floor is dominant; all the other reflected light can be ignored.
3. There is no direct light from any source to any sensor.
4. The floor and object are both Lambertian and flat (object heights can be ignored relative to the room height).

Assume that the incoming luminous (photon) flux per unit area at floor location (x, y) is $I(x, y)$. Clearly, $I(x, y)$ is the sum of luminous fluxes from all light sources:

$$I(x, y) = \sum_{j=1}^{N_f} I_j(x, y) \quad (2.1)$$

where $I_j(x, y)$ is the flux from source number j and N_f is the number of light sources (fixtures). For a downward-facing, point light source, we have

$$I_j(x, y) = f(j) \cdot I_{\max} \cdot q(\beta_j) \cdot \frac{\cos \beta_j}{4\pi D_j^2} \quad (2.2)$$

where $f(j)$ is the relative intensity of source number j scaled to lie in range $[0, 1]$, I_{\max} is the maximum intensity of the light source, β_j and D_j are as shown in Fig. 2-1, and $q(\cdot)$ is the light intensity distribution function that describes the relative intensity of the light from the source at each angle. An example of a $q(\cdot)$ function is shown in Fig. 2-2.

The luminous flux captured by lensless sensor number i (i.e., sensor i 's reading) is:

$$s(i) = b(i) + \int_0^W \int_0^L \frac{I(x, y) \alpha(x, y) \cos^2 \theta_i}{4\pi(H^2 + l_i^2)} S dx dy \quad (2.3)$$

Figure 2.2: Example of a light intensity distribution function $q(\cdot)$. An estimate of the $q(\cdot)$ function is obtained by 1) measuring luminous fluxes at several discrete angles using a Lux meter pointing towards the light source with a fixed distance; 2) averaging measurements corresponding to the same angles and normalizing the averaged measurements; and 3) performing piece-wise cubic interpolation for the value of $q(\cdot)$ at any real-valued angle in range $[0^\circ, 90^\circ]$.

where $\alpha(x, y)$ is the floor albedo at location (x, y) , S is the area of the sensor, $b(i)$ is the ambient light that arrives at sensor i , and W , L and H are the width, length and height of the room, respectively. Eq. (2.3) is derived under the assumption of small (negligible) sensor area S . Note that θ_i and l_i in Fig. 2.1 are functions of x and y .

To develop our localization algorithms, we make the simplifying assumption that the change in albedo $\Delta\alpha$ on the floor due to the appearance of an object has support that is a small, compact, connected region \mathcal{P} . Then, if $b(i)$ remains constant, the change in the reading of sensor i caused by the object appearance is:

$$\Delta s(i) = \int_{\mathcal{P}} \frac{I(x, y) \Delta\alpha(x, y) \cos^2 \theta_i}{4\pi(H^2 + l_i^2)} S dx dy. \quad (2.4)$$

The light reflection model is used as the basis of our indoor localization algorithms in both passive and active scene illumination. Both of our algorithms localize the *change* between the current state (e.g., room occupied by an object) and an initial

state (e.g., empty room) and therefore require one set of measurements for each state.

We note that our modeling assumptions, stated at the beginning of this section, are used only to *derive* our localization algorithms. They may not hold exactly in practice and indeed they do not in our physical testbed. Still, as we will see, our active-illumination-based localization algorithm performs consistently very well in our testbed indicating its robustness to deviations from the stated assumptions. Our empirical results validate the practical utility of our modeling assumptions despite their imperfections.

2.2 Localization *via* passive illumination

In order to develop a localization algorithm based on passive illumination, we make the following assumptions in addition to those listed in Section 2.1:

1. Besides ambient light, the intensities of all light sources also remain the same in the empty and occupied room states.
2. The object size is negligible compared to the floor size.

Under the above assumptions, the integral in (2.4) reduces to:

$$\Delta s(i) = \frac{I(x_0, y_0) \Delta \alpha(x_0, y_0) \cos^2 \theta_i}{4\pi(H^2 + l_i^2(x_0, y_0))} \cdot S \cdot S_0 \quad (2.5)$$

where (x_0, y_0) is the location of object's center, S_0 is the area of region \mathcal{P} , and $S_0 \ll W \times L$. For sensors number i_1 and i_2 , the ratio of the captured changes Δs is

$$\frac{\Delta s(i_1)}{\Delta s(i_2)} = \frac{(H^2 + l_{i_2}^2) \cos^2 \theta_{i_1}}{(H^2 + l_{i_1}^2) \cos^2 \theta_{i_2}} = \frac{(H^2 + l_{i_2}^2)^2}{(H^2 + l_{i_1}^2)^2} \quad (2.6)$$

so that the relationship between l_{i_1} and l_{i_2} simplifies to:

$$\frac{H^2 + l_{i_1}^2}{H^2 + l_{i_2}^2} = \sqrt{\frac{\Delta s(i_2)}{\Delta s(i_1)}} \quad (2.7)$$

If we substitute the 2D coordinates of sensors i_1 and i_2 on the ceiling $((X_{i_1}, Y_{i_1})$ and $(X_{i_2}, Y_{i_2}))$ and object location (x_0, y_0) into equation (2.7) to replace l_{i_1} and l_{i_2} , the equation can be re-written as a quadratic equation in x_0 and y_0 :

$$a_{i_1 i_2} x_0^2 + b_{i_1 i_2} x_0 + c_{i_1 i_2} y_0^2 + d_{i_1 i_2} y_0 = u_{i_1 i_2} \quad (2.8)$$

where

$$\begin{aligned} a_{i_1 i_2} &= 1 - \sqrt{\frac{\Delta s(i_2)}{\Delta s(i_1)}}, \\ b_{i_1 i_2} &= 2 \left(\sqrt{\frac{\Delta s(i_2)}{\Delta s(i_1)}} \cdot X_{i_2} - X_{i_1} \right), \\ c_{i_1 i_2} &= 1 - \sqrt{\frac{\Delta s(i_2)}{\Delta s(i_1)}}, \\ d_{i_1 i_2} &= 2 \left(\sqrt{\frac{\Delta s(i_2)}{\Delta s(i_1)}} \cdot Y_{i_2} - Y_{i_1} \right), \\ u_{i_1 i_2} &= \sqrt{\frac{\Delta s(i_2)}{\Delta s(i_1)}} \cdot (H^2 + X_{i_2}^2 + Y_{i_2}^2) - (H^2 + X_{i_1}^2 + Y_{i_1}^2) \end{aligned} \quad (2.9)$$

are coefficients derived from equation (2.7) that depend on sensor coordinates and the ratio of sensor reading changes.

In a room with N_s sensors, we can write $N_s - 1$ non-redundant quadratic equations corresponding to the sensor pairs $(i_1, i_2) = (1, 2), (1, 3), \dots, (1, N_s)$. Collecting coefficients from equations (2.8) for all sensor pairs as follows:

$$M = \begin{bmatrix} a_{12} & b_{12} & c_{12} & d_{12} \\ a_{13} & b_{13} & c_{13} & d_{13} \\ \vdots & \vdots & \vdots & \vdots \\ a_{1N_s} & b_{1N_s} & c_{1N_s} & d_{1N_s} \end{bmatrix}, \quad \mathbf{u} = \begin{bmatrix} u_{12} \\ u_{13} \\ \vdots \\ u_{1N_s} \end{bmatrix}. \quad (2.10)$$

we can find the object location (x_0, y_0) , that is encoded in vector $\mathbf{v} = [x_0^2, x_0, y_0^2, y_0]^T$, by solving $M\mathbf{v} = \mathbf{u}$. Since this set of equations may not be satisfied exactly due to noise and modeling imperfections, we apply constrained least-squares minimization

to find \mathbf{v} as follows:

$$\begin{aligned} \mathbf{v}^* &= \arg \min_{\mathbf{v}} \|M\mathbf{v} - \mathbf{u}\|_{l_2}^2 \\ \text{s.t. } \mathbf{v} &\geq 0, \mathbf{v} \leq [W^2, W, L^2, L]^T. \end{aligned} \quad (2.11)$$

The 2-nd and 4-th entries of the solution vector, provide an estimate of the object location (\hat{x}_0, \hat{y}_0) . The cost function is strictly convex and has unique global minimum when matrix M has full column rank ($N_s \geq 5$). The pseudo-code for this algorithm appears in Algorithm 1.

Algorithm 1: Localization *via* Passive Illumination

Input : Vectors of sensor readings: \mathbf{s}_0 for empty room and \mathbf{s} for occupied room, room dimensions W , L and H , sensor coordinates (x_i, y_i, H) for $i = 1, \dots, N_s$

Output: Estimated location (\hat{x}_0, \hat{y}_0)

- 1 Let $\Delta\mathbf{s} \leftarrow \mathbf{s} - \mathbf{s}_0$;
 - 2 Calculate coefficients $a_{i_1 i_2}, b_{i_1 i_2}, c_{i_1 i_2}, d_{i_1 i_2}, u_{i_1 i_2}$ for $(i_1, i_2) = (1, 2), (1, 3), \dots, (1, N_s)$ in (2.8);
 - 3 Construct matrix M and vector \mathbf{u} as in (2.10);
 - 4 Use quadratic programming to find the optimal solution \mathbf{v}^* to minimization (2.11);
 - 5 Estimated location: $(\hat{x}_0, \hat{y}_0) \leftarrow (v_2^*, v_4^*)$.
-

2.3 Experiments

We have tested the performance of our passive-illumination-based localization algorithm in both simulated and real-world experiments. We performed simulations in MATLAB and Unity3D, a video game development environment. For our real-world experiments, we have built a small-scale testbed using a network of synchronized small LED light sources and single-pixel color sensors. We tested our algorithm in the ideal case, under illumination change between the empty and occupied room states,

and also in the presence of noise in sensor readings. Detailed information about our experimental setup, testbed, and results can be found on our project’s web page¹.

2.3.1 Experimental setup

We built a testbed room with size $W=122.5\text{cm}$, $L=223.8\text{cm}$ and $H=70.5\text{cm}$ and 9 identical source-sensor modules placed on the ceiling on a 3×3 grid (Fig. 2-3). In simulation experiments, the room size and source/sensor locations are set to be identical to our testbed. Each module contains an LED light source and a single-pixel light sensor. The light sources will be modulated in experiments with active illumination algorithms, as we will see in the next chapter. For passive illumination, we simply turned on all light sources at their maximum intensity and kept them unchanged to produce constant light.

Figure 2-3: Layout of source-sensor modules on the ceiling.

We used flat (negligible height) rectangular objects of 6 different sizes (Table 2.1). Our object size choices are quite realistic at room-scale. For example, if we scale the

¹<http://vip.bu.edu/projects/vsns/privacy-smartroom/active-illumination/>

testbed area 8-fold to a room of dimensions about 3.5×6 m, then our smallest object (1x) will be about the size of a small plate (14cm diameter) and our largest object (64x) will be about the size of a table (70×140 cm). We placed the objects on the floor so that their sides are parallel to those of the room.

Table 2.1: Dimensions of rectangular objects used in experiments.

Relative Size	Width (cm)	Length (cm)
64x	25.8	51.1
32x	25.8	25.5
16x	12.9	26.0
8x	12.9	13.0
4x	6.4	12.9
1x	3.2	6.4

2.3.2 Simulation Experiments

To validate our active and passive illumination algorithms, we simulated the room with light sources and sensors in both MATLAB and Unity3D, a game development environment that can simulate realistic scenes.

In MATLAB simulation, we generated the floor albedo maps $\alpha(x, y)$ for empty and occupied states, and then calculated the sensor readings in each state using equations (2.1), (2.2) and (2.3). The MATLAB simulations are idealized since the sensor readings match the light reflection model perfectly with no inconsistencies.

In Unity3D simulation, we simulated the LED light sources using Unity3D’s built-in point light source. However, the built-in point light source is omnidirectional and does not support a light intensity distribution function $q(\cdot)$. Therefore, we placed a spherical cover around each light source. The cover is semi-transparent and blocks parts of the light from the source. We set the transparency of the cover at different angles differently in order to match the $q(\cdot)$ function. To simulate a light sensor, we placed Unity3D’s virtual camera on the ceiling looking downward. The sensor reading

(a) Simulation of a light source with object placed on the floor

(b) Top view of the scene

Figure 2-4: Illustration of a Unity3D scene used in experiments.

is a weighted average of the camera’s pixel values, where the weight is each pixel’s solid angle to the center of the camera lens. To simulate sunlight (as part of ambient illumination), we used a directional light source which produces parallel rays.

An illustration of a Unity3D scene of the room is shown in Fig. 2-4. The Unity3D model is only used to collect data while the localization algorithms are implemented in MATLAB.

In both MATLAB and Unity3D, we uniformly set the albedo of the floor to 0.5 and of the object to 0. We placed the center of the object at 20 different locations equally-spaced on a 5×4 grid (Fig. 2-5). We evaluated our algorithm’s performance in terms of localization error defined as the Euclidean distance between the true and estimated locations. First, we evaluated the performance of our algorithm for different object sizes, in both simulation environments, without noise. The mean and standard deviation of the localization errors with respect to the object size are shown in Fig. 2-6. We note that our passive illumination algorithm works better for smaller objects, which is consistent with the negligible object size assumption (assumption 2 in Section 2.2) used to derive this algorithm.

We also tested the robustness of our passive illumination algorithm under illumi-

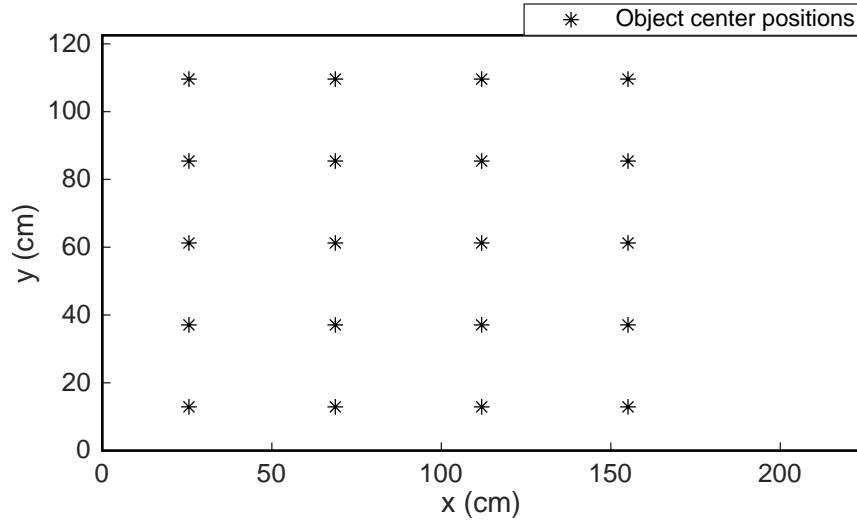

Figure 2-5: 20 locations on the floor where we placed the center of the objects.

nation change in Unity3D. An illumination change refers to the change of ambient light level $b(i)$ (Eq. 2.3) between the empty and occupied room states. We performed tests using the 64x object, and turned on/off the simulated sun light to mimic day and night. The results are shown in Fig. 2-7. When there is an illumination change, the performance of the algorithm gets significantly worse. This was to be expected since the passive illumination algorithm assumes that the only change in the sensor readings is caused by the object; it cannot handle illumination changes.

Furthermore, we tested the effect of sensor noise on the performance of our algorithms. We assumed that the noise corrupting each sensor reading is an independent and identically-distributed, zero-mean Gaussian. In MATLAB simulation, we added noise to all sensor readings in both the empty and occupied room states. We used the 16x object, and we varied the standard deviation of noise from 10^{-4} to 10^{-3} in 10^{-4} increments. (10^{-3} represents about 6.84% of the maximum change in any sensor's reading between empty and occupied room states.) Fig. 2-8 shows the mean and stan-

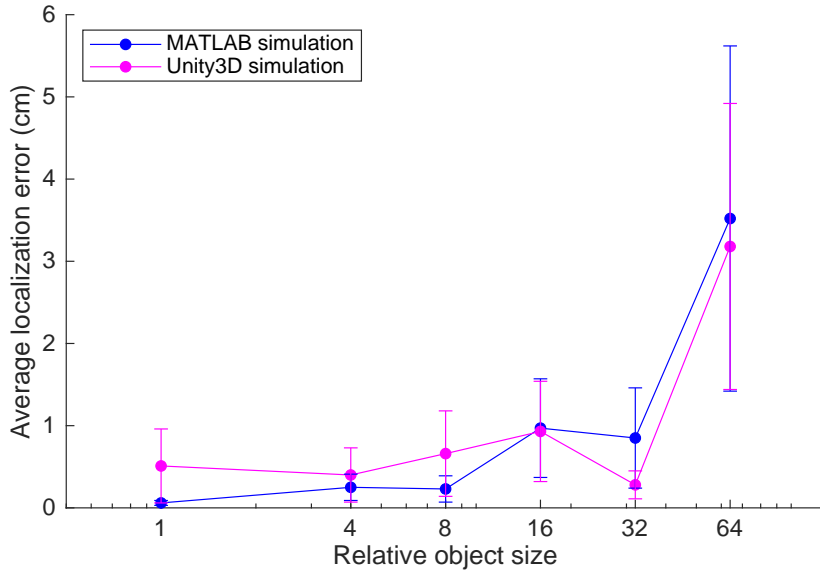

Figure 2-6: Mean and standard deviation of localization errors of our passive illumination algorithm with respect to the relative object size in both MATLAB and Unity3D simulations. The dots represent average localization errors, while the bars indicate the standard deviation of errors for each object size.

standard deviation of localization errors for passive and active illumination algorithms as a function of the standard deviation of noise. Although the magnitude of noise is small compared with that of the signal (sensor reading changes between empty and occupied states), the average localization error increases and saturates quickly as the noise level increases, which suggests that the passive illumination algorithm is very sensitive to noise. This is because the equation (2.6) is based on the ratio of sensor reading changes and therefore the noise will be magnified.

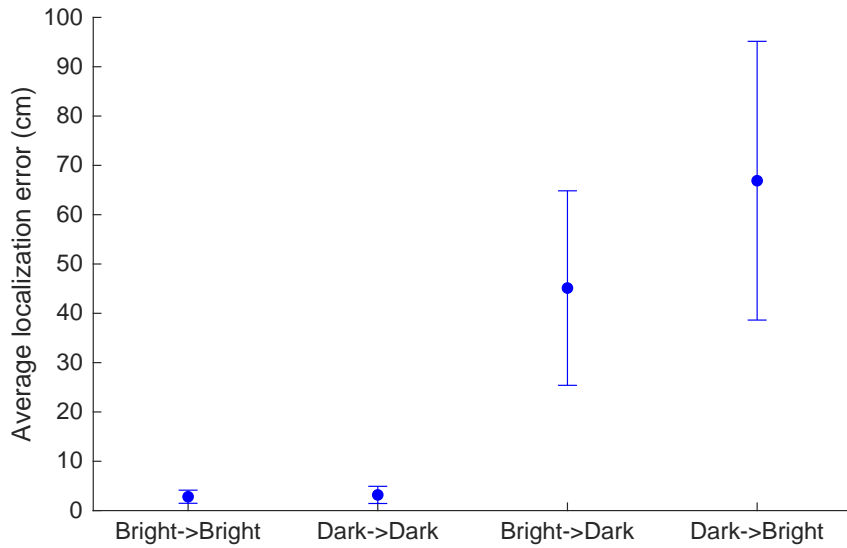

Figure 2.7: Mean and standard deviation of localization errors of the passive illumination algorithm for all lighting combinations in Unity3D simulation (empty room \rightarrow occupied room).

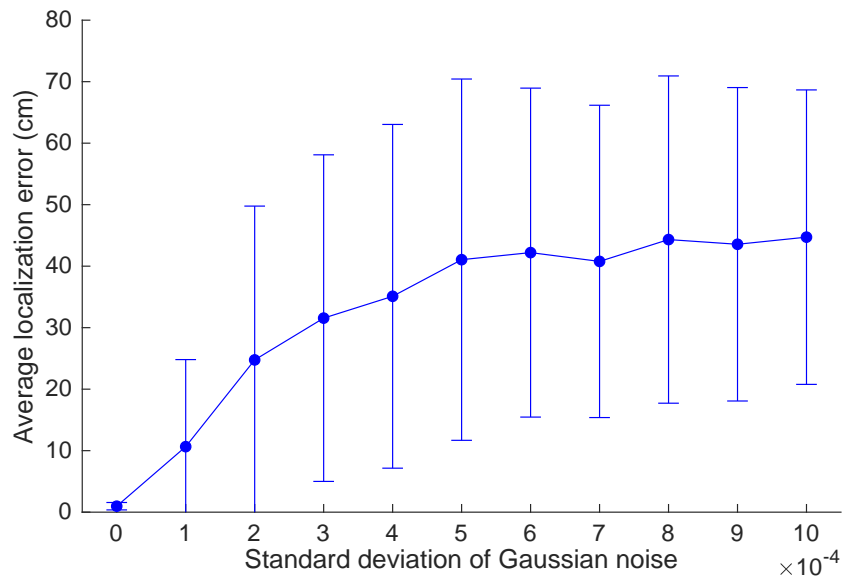

Figure 2.8: Mean and standard deviation of localization errors of our passive illumination algorithm with respect to the standard deviation of Gaussian noise in MATLAB simulation. The mean and standard deviation of errors at each noise level are calculated by combining results from 3 repetitions of the experiment.

2.3.3 Testbed Experiments

To test our approach in a real-world setting, we built a room mock-up using a white rectangular foam board as the floor and a 3×3 array of ceiling-mounted light source-sensor modules. Each module consists of a Particle Photon board controlling an LED and a single-pixel light sensor. We estimated the $q(\cdot)$ function following the process described in Fig. 2-2. We note that the sensors have no lens and measure photon flux not radiance. A photo of our testbed is shown in Fig. 2-9. This is a small-scale proof-of-concept testbed to quantitatively validate the feasibility of active-illumination based indoor localization. Although idealized (no walls/furniture, floor and objects have uniform albedo), it is a much-needed first step before developing a full-scale smart-room testbed. While this is not an accurate representation of complex real-world scenarios, it does capture real-world non-idealities such as sensor noise, non-Lambertian surfaces, indirect light, and fluorescent light flicker and provides insights into the localization accuracy relative to testbed dimensions.

During data collection, the LEDs turn on all 4 channels (red, green, blue and white) at maximum intensity and the single-pixel sensors record readings from the white channel only (red, green and blue channel readings are ignored). When a sensor records, it takes 4 consecutive readings which are then averaged together to reduce noise. This process yields 9 noise-reduced sensor readings in the passive illumination case.

Similar to the simulation experiments, we tested our algorithm in the testbed for different object sizes (from 8x to 64x) at all 20 locations. We did not use the 1x and 4x objects because their sensor reading changes are too small and get buried in noise. We recorded data in a completely dark room with no ambient illumination (fluorescent lights off).

As shown in Fig. 2-10, the performance of our passive illumination algorithm gets

Figure 2-9: Photo of our testbed with the 64x flat object. Due to the limited intensity of light sources, we hang a board in mid-air as a proxy for the floor and thus to increase the reflected light intensity.

much worse compared with that in simulation experiments. As Fig. 2-8 suggests, this is likely due to the high sensitivity of the passive illumination algorithm to sensor noise. In order to verify this hypothesis, we first measured the standard deviation of the readings of each sensor from the testbed data. Then, in `MATLAB` simulation, we added Gaussian noise (having the same relative standard deviations as in the testbed) to the readings of the corresponding sensors in both empty and occupied room states, and ran the passive illumination algorithm. For each ground truth location, we ran the simulation 3 times. The localization errors are shown in Table 2.2. We see that the performance of the passive illumination algorithm in `MATLAB` simulation under noise is similar to its performance in the testbed. This suggests that noise is the main reason why passive illumination performs poorly.

Finally, we tested the robustness of the passive illumination algorithm under illu-

Figure 2-10: Mean and standard deviation of localization errors of our passive illumination algorithm with respect to the relative object size on the real testbed.

mination change using the 64x object. We applied different ambient lighting combinations for the empty and occupied room states (fluorescent lights on or off). As can be seen in Fig. 2-11, the passive illumination algorithm with illumination change performs only slightly worse than without illumination change. This is not unexpected since its performance without illumination changes was already poor (Fig. 2-10).

Figure 2-11: Mean and standard deviation of localization errors of the passive illumination algorithm for all lighting combinations on the real testbed (empty room \rightarrow occupied room). Results are for the 64x object.

2.4 Summary

In this chapter, we proposed a localization algorithm *via* passive illumination. Our passive illumination algorithm can localize a flat object accurately in idealized simulations in MATLAB and Unity3D (average localization error $\leq 4\text{cm}$ on a floor of size $122.5\text{cm} \times 223.8\text{cm}$), but it is very sensitive to sensor reading noise and ambient illumination changes. It also has poor performance on the real testbed due to real-world non-idealities. This is expected since it assumes that the sensor reading changes are only due to object presence.

Chapter 3

Model-based indoor localization *via* active scene illumination

In this chapter, we will introduce our proposed model-based localization algorithms *via* active illumination. With the use of an array of modulated LED light sources, our active illumination algorithms are supposed to be more robust to noise and illumination change than the passive illumination algorithm developed in Chapter 2.

3.1 Active illumination methodology

Fig. 3-1 provides an overview of the active illumination methodology. Compared with a passive illumination system using constant light sources, our active illumination system modulates the light sources and measures responses from single-pixel sensors.

The sensor responses are results of 1) light modulation pattern, 2) ambient light intensity and noise, and 3) shapes, locations and surface properties of all objects in the room. Ambient light intensity may vary, but since light sources can be modulated, we can easily measure and eliminate the contribution of ambient light. Therefore, the relationship between light modulation and sensor responses is purely determined by the room state. The localization algorithm will then compute the difference of current room state from a background (e.g., empty room) and estimate the location of the object that causes the change.

Figure 3-1: Illustration of the active illumination methodology.

Consider light source with index j and sensor with index i . Define

$$A(i, j) = \int_0^W \int_0^L \frac{I_{\max} S q(\beta_j) \cos \beta_j \cos^2 \theta_i \alpha(x, y)}{16\pi^2 D_j^2 (H^2 + l_i^2)} dx dy \quad (3.1)$$

where β_j , D_j , θ_i and l_i are functions of x and y and are shown in Fig. 2-1. If we substitute Eq. (2.1), Eq. (2.2) and Eq. (3.1) into Eq. (2.3), we get

$$s(i) = b(i) + \sum_{j=1}^{N_f} f(j) A(i, j) \quad (3.2)$$

where $f(j)$ is the relative intensity of light source j scaled to range $[0, 1]$. Eq. (3.2) implies that sensor i 's reading is the sum of contributions of all light sources and ambient light. The meaning of $A(i, j)$ is the contribution of source j to the reading of sensor i per unit light intensity. It is clear from equation (3.1) that $A(i, j)$ is determined by room geometry, material properties and source and sensor locations,

but it is not affected by ambient light. Suppose we have N_f light sources and N_s sensors. Then, we can rewrite Eq. (3.2) in matrix form:

$$\mathbf{s} = \mathbf{A}\mathbf{f} + \mathbf{b} \quad (3.3)$$

where \mathbf{s} is an $N_s \times 1$ vector of sensor readings, \mathbf{f} is an $N_f \times 1$ vector of relative source intensities, and \mathbf{b} a vector of ambient light levels at each sensor. A is an $N_s \times N_f$ matrix whose ij -th entry is $A(i, j)$ in Eq.(3.1). We call matrix A the **light transport matrix**.

We further relate $A(i, j)$ to floor reflectivity (albedo). Let

$$C(i, j; x, y) = \frac{I_{\max} S q(\beta_j) \cos \beta_j \cos^2 \theta_i}{16\pi^2 D_j^2 (H^2 + l_i^2)} \quad (3.4)$$

then

$$A(i, j) = \int_0^w \int_0^L C(i, j; x, y) \alpha(x, y) dx dy. \quad (3.5)$$

The meaning of $C(i, j; x, y)$ is the light contribution of source j to the reading of sensor i via floor location (x, y) with unit light source intensity and unit floor albedo. It can be seen from Eq. (3.4) that $C(i, j; x, y)$ is a function of room height, light intensity distribution function $q(\cdot)$, locations of source j and sensor i , and floor position (x, y) . It is completely determined by the characteristics of room, light sources and sensors, and once we have this information, we can calculate $C(i, j; x, y)$ without modulating sources and measuring with sensors.

Suppose we have obtained light transport matrices for two room states: A_0 when the room is empty, and A when an object is placed somewhere in the room. Taking

the difference between the ij -th entries of the two light transport matrices, we get:

$$\Delta A(i, j) = A(i, j) - A_0(i, j) = \int_0^W \int_0^L C(i, j; x, y) \Delta\alpha(x, y) dx dy \quad (3.6)$$

where $\Delta\alpha(x, y)$ is the change of floor albedo between the two states at position (x, y) . Albedo change is usually the result of object appearance, and in the case of a single object, it should be concentrated in one connected blob. If we discretize the floor plane into a grid with spacing δ , we can re-write the discretized approximation to Eq. (3.6) in matrix and vector form as follows:

$$\Delta\mathbf{A} = \delta^2 C \Delta\boldsymbol{\alpha} \quad (3.7)$$

where vector $\Delta\mathbf{A}$ contains lexicographically-scanned elements of matrix ΔA , $\Delta\boldsymbol{\alpha}$ is a vector of albedo changes at all locations (x, y) on the discretized floor grid, and C is a matrix of $C(i, j; x, y)$ values, whose rows correspond to source-sensor pairs (i, j) and columns correspond to positions (x, y) . We call matrix C the **light contribution matrix**. The length of vector $\Delta\boldsymbol{\alpha}$ (i.e. the number of columns of matrix C) is determined by the discretization stepsize δ , and in our experiments, $\Delta\boldsymbol{\alpha}$ has length of $\lfloor \frac{W}{\delta} \rfloor \times \lfloor \frac{L}{\delta} \rfloor$.

The light contribution matrix C can be calculated up to a constant factor given room dimensions, light source and sensor locations and light intensity distribution function $q(\cdot)$ (Fig. 2.2). The light transport matrices A for empty and occupied room states can be obtained from two sets of sensor measurements in corresponding room states, which we will discuss in the next section. The goal is to estimate the albedo change map on the floor (vector $\Delta\boldsymbol{\alpha}$) and then estimate the object location. In Section 3.3, we will propose two variants of localization algorithm based on based on this active illumination methodology. Both variants follow the assumptions of the light reflection model, as stated in Section 2.1.

3.2 Obtaining light transport matrix A

The light transport matrix A can be estimated *via* light source modulation. In an active illumination system, we can specify the intensity $f(j)$ of any light source j to any value in range $[0, 1]$.

Suppose we have specified the intensities of all light sources as a vector \mathbf{f}_0 (base light). Then, by Eq. (3.3), we can obtain a vector of sensor readings under base light $\mathbf{s}_0 = A\mathbf{f}_0 + \mathbf{b}$. Assume that the contribution of ambient light \mathbf{b} remains constant during the light modulation process. If we add some perturbation $\Delta\mathbf{f}$ to the base light \mathbf{f}_0 , the sensor reading will become $\mathbf{s} = A(\mathbf{f}_0 + \Delta\mathbf{f}) + \mathbf{b}$. Taking the difference of the two sets of sensor readings, we get

$$\Delta\mathbf{s} = \mathbf{s} - \mathbf{s}_0 = A\Delta\mathbf{f} \quad (3.8)$$

so that the contribution of ambient light \mathbf{b} is eliminated.

To obtain the matrix A , we need to design a set of perturbations that form a basis. Therefore, we need a base light vector and n perturbations at times t_1, t_2, \dots, t_n where $n \geq N_f$. Let matrix $\Delta F = [\Delta\mathbf{f}(t_1), \Delta\mathbf{f}(t_2), \dots, \Delta\mathbf{f}(t_n)]$ and the corresponding sensor reading changes $\Delta S = [\Delta\mathbf{s}(t_1), \Delta\mathbf{s}(t_2), \dots, \Delta\mathbf{s}(t_n)]$. Then, by Eq. (3.8), we have

$$\Delta S = A\Delta F \quad (3.9)$$

and

$$\Delta S \Delta F^T = A \Delta F \Delta F^T. \quad (3.10)$$

We can estimate A by multiplying $(\Delta F \Delta F^T)^{-1}$ on both sides:

$$A = \Delta S \Delta F^T (\Delta F \Delta F^T)^{-1}. \quad (3.11)$$

For convenience, we call a light intensity vector \mathbf{f} with specified values a **light state**, and call a set of light states (including base light vector and base light + all perturbations) a **light pattern**. In our experiments, we use a light pattern where the base light is all-zero and each perturbation is a one-hot vector (one light source on at maximum intensity). Therefore, our light pattern has $N_f + 1$ light states.

Although constant ambient illumination is not an assumption of localization *via* active illumination, it does assume that the ambient light should stay constant during modulation through the entire light pattern so that its contribution can be eliminated. This assumption is easy to satisfy for gradually-changing ambient light sources (e.g., sunlight) since the modulation-response time is short; however, ambient light sources that flicker (e.g., fluorescent light) or a sudden change of ambient illumination (e.g., turning on/off an ambient light source) will violate this assumption and bring noise into the estimated light transport matrix. Another problem with light modulation is that the modulation process itself will produce visible flickers to human eyes, causing discomfort, if the modulation frequency of a light source is below 60Hz. The solution to both issues is to increase the light modulation frequency; however, the modulation frequency is limited by the minimum integration time needed for a sensor to get a stable reading. We will ignore these issues in this dissertation, since we are presenting a proof-of-concept study rather than a commercial product.

3.3 Localization *via* active illumination

In this section, we will introduce our proposed localization algorithm *via* active illumination. Given light transport matrices A_0 for empty room, A for occupied room and light contribution matrix C , our algorithm will estimate the change of albedo $\Delta\alpha$ and then estimate the location of the object. We will propose two variants of the algorithm using different penalty functions.

3.3.1 LASSO algorithm

Eq. (3.7) is usually an underdetermined system; the number of unknowns (number of points on the discretized floor grid) is usually larger than the number of equations (number of light source-sensor pairs). Therefore, the solution to $\Delta\boldsymbol{\alpha}$ is not unique. To obtain an accurate estimate of $\Delta\boldsymbol{\alpha}$ which is close to the ground truth, an additional constraint is required.

Since object size is usually small compared to room size, we can start by assuming that $\Delta\boldsymbol{\alpha}$ is a sparse vector. Inspired by LASSO regression, we add the l_1 -norm on $\Delta\boldsymbol{\alpha}$ to the error function to promote sparsity and solve the following convex optimization problem:

$$\Delta\boldsymbol{\alpha}^* = \arg \min_{\Delta\boldsymbol{\alpha}} \left[\|\Delta\mathbf{A} - \delta^2 C \Delta\boldsymbol{\alpha}\|_{l_2}^2 + \lambda \delta^2 \|\Delta\boldsymbol{\alpha}\|_{l_1} \right] \quad (3.12)$$

where λ is the weight of the l_1 penalty term. Given the value of λ , the problem (3.12) can be solved with a gradient descent optimization algorithm. In our experiments we used the CVX package, a MATLAB toolkit for convex programming¹. A larger λ will promote the solution $\Delta\boldsymbol{\alpha}^*$ to have fewer non-zero entries, and vice versa. The value of λ can be optimized using a grid search, where the best λ will minimize the average localization error.

After estimating the albedo change $\Delta\boldsymbol{\alpha}^*$, the location of the object that causes the albedo change is estimated as the centroid of the magnitude of $\Delta\boldsymbol{\alpha}^*$:

$$\begin{aligned} \hat{x}_0 &= \frac{\sum_{x,y} x \cdot |\Delta\boldsymbol{\alpha}^*(x,y)|}{\sum_{x,y} |\Delta\boldsymbol{\alpha}^*(x,y)|}, \\ \hat{y}_0 &= \frac{\sum_{x,y} y \cdot |\Delta\boldsymbol{\alpha}^*(x,y)|}{\sum_{x,y} |\Delta\boldsymbol{\alpha}^*(x,y)|}. \end{aligned} \quad (3.13)$$

Estimating object location using centroid of albedo change is accurate under the assumption that albedo change is uniform within the object area. This assumption

¹<http://cvxr.com/cvx/>

is easily satisfied if both the floor and the object have a uniform albedo. When the texture of the floor or the object gets complicated (e.g., floor with colorful tiles), this estimation will introduce errors, but the estimated object location will likely still stay within the object area if the albedo change estimation is accurate enough.

The pseudo-code for this algorithm is shown in Algorithm 2.

Algorithm 2: Localization *via* Active Illumination - LASSO Algorithm

Input : Light transport matrices: A_0 for empty room and A for occupied room,
room dimensions W , L and H , all light source and sensor coordinates

Output: Estimated location (\hat{x}_0, \hat{y}_0)

- 1 Calculate light contribution matrix C where $C(i, j; x, y) = \text{const} \cdot \frac{q(\beta_j) \cos \beta_j \cos^2 \theta_i}{D_j^2 \cdot (H^2 + l_i^2)}$ for $i \in \{1, \dots, N_s\}$, $j \in \{1, \dots, N_f\}$, $x \in [0, L]$, $y \in [0, W]$ with spacing δ ;
 - 2 Let $\Delta \mathbf{A}$ be a vector form of $\Delta A = A - A_0$;
 - 3 Calculate the optimal solution $\Delta \boldsymbol{\alpha}^*$ for problem (3.12) without constraints;
 - 4 Estimated location: $(\hat{x}_0, \hat{y}_0) \leftarrow$ centroid of $|\Delta \boldsymbol{\alpha}^*|$.
-

3.3.2 Localized ridge regression algorithm

The l_1 penalty term in the LASSO algorithm (Algorithm 2) tends to create spikes in the resulting albedo change map $\Delta \boldsymbol{\alpha}$ (Fig. 3.3 (a)(c)). This might be a good estimation for small objects, but for larger objects this estimated map will become too sparse. Therefore, we propose another version of the active illumination algorithm using the squared l_2 norm of $\Delta \boldsymbol{\alpha}$ as the penalty term, similar to ridge regression. The optimization problem becomes as follows:

$$\Delta \boldsymbol{\alpha}_0^* = \arg \min_{\Delta \boldsymbol{\alpha}} \left[\|\Delta \mathbf{A} - \delta^2 C \Delta \boldsymbol{\alpha}\|_{l_2}^2 + \sigma \delta^2 \|\Delta \boldsymbol{\alpha}\|_{l_2}^2 \right]. \quad (3.14)$$

The squared l_2 penalty term penalizes large entries in $\Delta \boldsymbol{\alpha}$, and therefore helps generate a more smooth albedo change map. σ is a weight of the l_2 penalty term

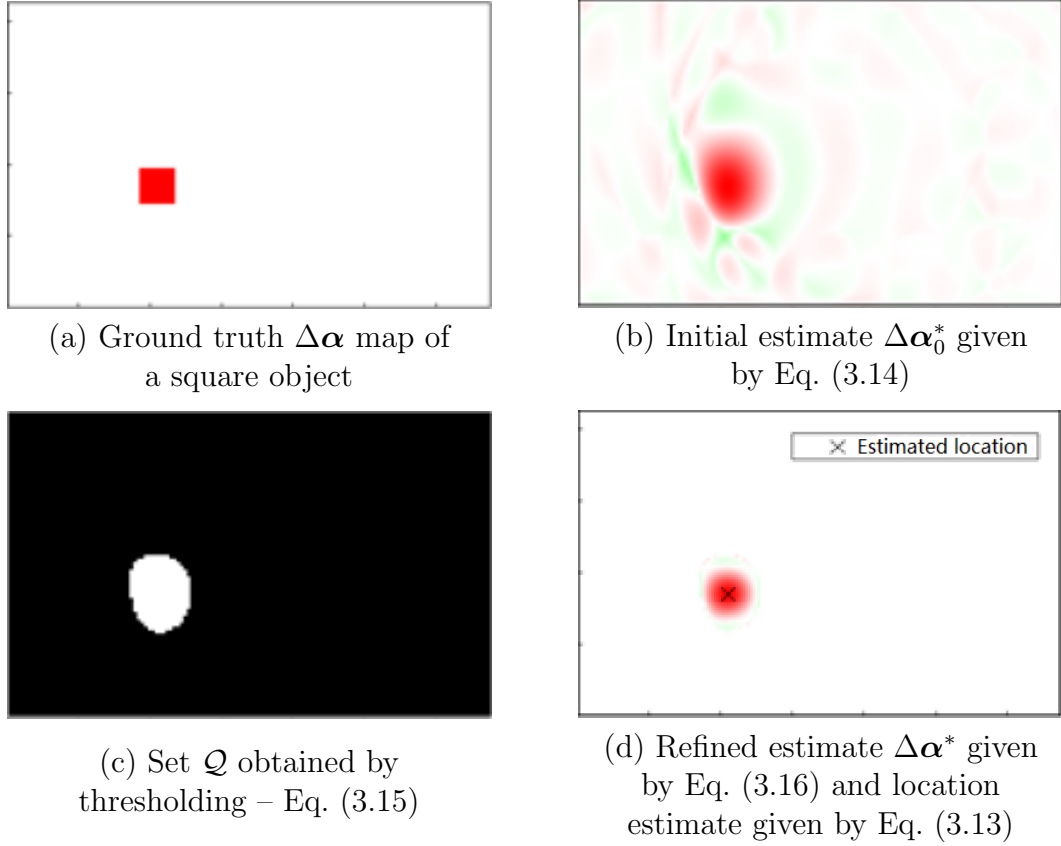

Figure 3-2: Sample ground-truth albedo change, initial estimate, thresholding and refined estimate using the localized ridge regression algorithm. Red: positive $\Delta\alpha$, green: negative $\Delta\alpha$.

controlling the smoothness of the albedo change estimate. The optimal $\Delta\alpha_0^*$ for (3.14) is a coarse estimate of the actual albedo change, with wavy patterns on the entire floor outside the object area (Fig. 3-2(b)). The estimated object location using the centroid of $|\Delta\alpha_0^*|$ will be biased towards the center of floor, as the $|\Delta\alpha_0^*|$ map is mostly non-zero. To refine the localization result, we threshold $|\Delta\alpha_0^*|$ normalized by its maximum magnitude to obtain a set of locations

$$\mathcal{Q} = \left\{ (x, y) : \frac{|\Delta\alpha_0^*(x, y)|}{\max_{(x, y)} |\Delta\alpha_0^*(x, y)|} \geq \tau \right\} \quad (3.15)$$

where the change in albedo is relatively large. These are likely to correspond to

the area where the object appeared. Then, in the second step, we solve the ridge regression problem again, but the solution is now restricted to a subset of locations in \mathcal{Q} .

$$\begin{aligned} \Delta\boldsymbol{\alpha}^* &= \arg \min_{\Delta\boldsymbol{\alpha}} \left[\|\Delta\mathbf{A} - \delta^2 C \Delta\boldsymbol{\alpha}\|_{l_2}^2 + \sigma \delta^2 \|\Delta\boldsymbol{\alpha}\|_{l_2}^2 \right] \\ \text{s.t. } \Delta\boldsymbol{\alpha}(x, y) &= 0, \quad \forall (x, y) \notin \mathcal{Q} \end{aligned} \quad (3.16)$$

After obtaining the optimal $\Delta\boldsymbol{\alpha}^*$ from (3.16), we use the centroid of the $|\Delta\boldsymbol{\alpha}^*|$ map as the estimated object location (Eq. (3.13)).

Both optimization problems (3.14) and (3.16) are convex and so have a closed-form solution, which we derive in Appendix A. σ and τ are two parameters that affect the algorithm's performance, and we use grid search to find the best set of parameters yielding the minimum average localization error.

The pseudo-code for this algorithm appears in Algorithm 3 below. Fig. 3-2 shows a sample ground truth albedo change map and the results of each step in the localized ridge regression algorithm.

Algorithm 3: Localization *via* Active Illumination - Localized Ridge Regression Algorithm

Input : Light transport matrices: A_0 for empty room and A for occupied room, room dimensions W , L and H , all light source and sensor coordinates

Output: Estimated location (\hat{x}_0, \hat{y}_0)

- 1 Calculate light contribution matrix C where $C(i, j; x, y) = \text{const} \cdot \frac{q(\beta_j) \cos \beta_j \cos^2 \theta_i}{D_j^2 \cdot (H^2 + l_i^2)}$ for $i \in \{1, \dots, N_s\}$, $j \in \{1, \dots, N_f\}$, $x \in [0, L]$, $y \in [0, W]$ with spacing δ ;
 - 2 Let $\Delta\mathbf{A}$ be a vector form of $\Delta A = A - A_0$;
 - 3 Calculate the optimal solution $\Delta\boldsymbol{\alpha}_0^*$ for problem (3.14) without constraints;
 - 4 Threshold $|\Delta\boldsymbol{\alpha}_0^*|$ using τ to get the point set \mathcal{Q} ;
 - 5 Calculate the optimal solution $\Delta\boldsymbol{\alpha}^*$ for problem (3.16) with $\Delta\boldsymbol{\alpha}$ constrained inside \mathcal{Q} ;
 - 6 Estimated location: $(\hat{x}_0, \hat{y}_0) \leftarrow$ centroid of $|\Delta\boldsymbol{\alpha}^*|$.

3.3.3 Comparison of LASSO and Localized ridge regression algorithms

To compare the performance of the two active illumination algorithm variants on objects of different sizes, we did simulation experiments in **MATLAB**. The room size, light source and sensor locations and object sizes used are the same as those described in Section 2.3.1. We put each object at the 20 locations marked in Fig. 2.5, and compared the two algorithm variants in terms of estimated albedo change map and localization error. The parameters (λ for LASSO algorithm and σ and τ for localized ridge regression algorithm) are optimized for each object size to minimize the average localization error.

Fig. 3.3 shows sample albedo change and location estimates of both algorithm variants for 4x and 64x objects. It is seen from Fig. 3.3 that the LASSO algorithm gives higher localization errors since it tends to choose only a few representative columns of matrix C whose weighted sum is close to $\Delta\mathbf{A}$. The locations corresponding to these columns can be away from the object center. The localized ridge regression algorithm, on the other hand, tends to choose columns of matrix C inside a blob, and therefore gives a better estimate of the location and size of the object.

We then computed the mean and standard deviation of localization errors of both algorithm variants for all object sizes, which are shown in Fig. 3.4. The localization errors of the localized ridge regression algorithm are an order of magnitude smaller than those for the LASSO algorithm. Since the localized ridge regression algorithm outperforms the LASSO algorithm in all scenarios, we advocate the use of localized ridge regression algorithm and explore it in more detail in the following sections.

3.4 Comparison with localization *via* passive illumination

In Section 2.3 we demonstrated *via* simulation and testbed experiments that the passive illumination algorithm is accurate in ideal cases but sensitive to sensor noise and illumination changes. In this section, we will validate the accuracy and robustness of our active illumination algorithm *via* the same sets of experiments and compare it with the passive illumination algorithm.

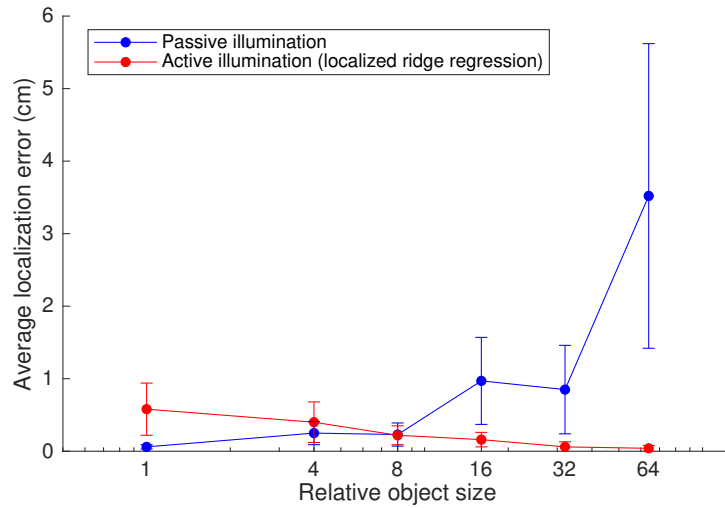

3.4.1 Simulation and testbed experiments

We first validated our active illumination algorithm (localized ridge regression) in **MATLAB** and Unity3D simulations in ideal case, with no noise or illumination changes. The room size, light source and sensor locations, object sizes and other experiment settings follow the experiments described in Section 2.3.2, except that the light sources are now modulated. In **MATLAB** simulations, we first generated the ground truth albedo change map $\Delta\alpha$ given object size and location, and then calculated the change of light transport matrix $\Delta\mathbf{A}$ using Eq. (3.7). In Unity3D simulations, we modulated the light sources with animation scripts, using the light pattern described in Section 3.2 to obtain the light transport matrices for empty and occupied room states, and then took the difference between the two to obtain $\Delta\mathbf{A}$. The light contribution matrix C is pre-computed and used in both types of simulations. We put each object at the 20 locations marked in Fig. 2-5. For each object size and simulation environment, we optimized the parameters σ and τ to minimize the average localization error.

Fig. 3-5 shows the mean and standard deviation of localization errors of passive and active illumination algorithms in both simulations. Unlike passive illumination, our active illumination algorithm favors larger object sizes, although its performance is slightly worse than that for the passive illumination algorithm for smaller objects. The **MATLAB** and Unity3D simulation results exhibit similar trends.

We then tested both algorithms' robustness to illumination changes and sensor noise in Unity3D and MATLAB simulations respectively, following the same procedure as described in Section 2.3.2. The localization errors for all ambient illumination scenarios are shown in Fig. 3-6 (a). The active illumination algorithm performs consistently well even when there is an illumination change between empty and occupied room states, which is expected. Fig. 3-6 (b) shows the localization errors versus the standard deviation of Gaussian noise in sensor readings. The active illumination algorithm is much more robust to noise, whose average localization error is almost an order of magnitude smaller than that of passive illumination as noise level increases.

Lastly, we validated our active illumination algorithm on the real testbed (Fig. 2-9). We collected data under the same lighting condition as when we tested the passive illumination algorithm (fluorescent light off). For empty room state, we ran the light modulation process for several cycles through the light pattern, and averaged the obtained light transport matrices to obtain A_0 . Then, for each object size from 8x to 64x, we put the object at all 20 locations and collected one light transport matrix A per location. Localization errors with respect to object size are shown in Fig. 3-7 (a). We also tested the algorithms' robustness to illumination changes by switching the fluorescent light in the room, and the results are shown in Fig. 3-7 (b). The active illumination algorithm performs well for all object sizes and under illumination changes on the testbed, which is consistent with the simulation results. Due to flicker in the fluorescent light, the active illumination algorithm has higher standard deviations of errors when the occupied room state is bright.

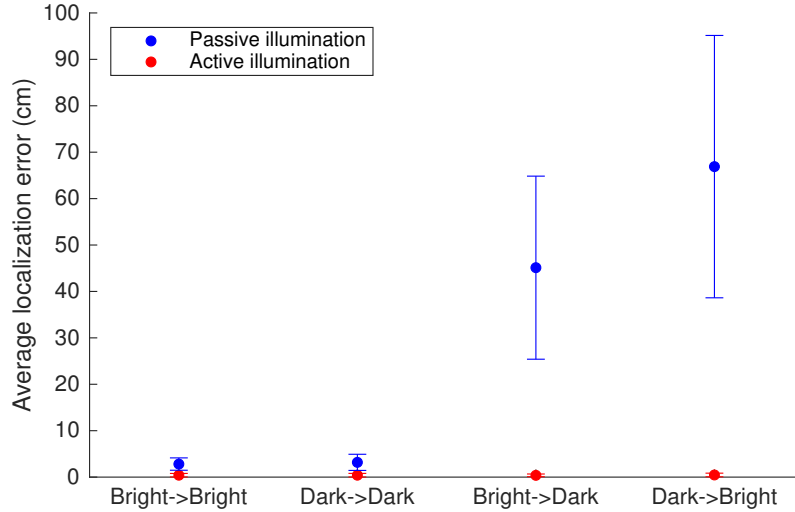

(a) MATLAB simulations

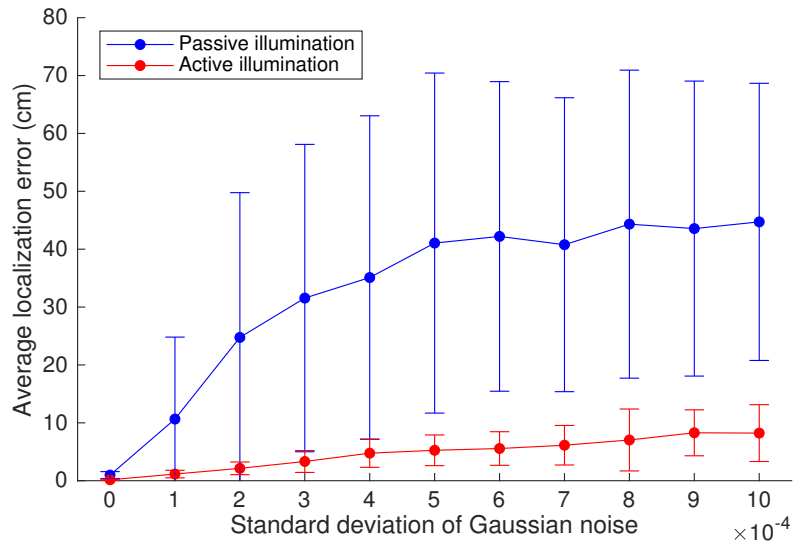

(b) Unity3D simulations

3.4.2 Discussion

Effect of object size: As suggested by Fig. 3-5, the active illumination algorithm performs better for larger objects but slightly worse for smaller ones. This is because the l_2 penalty term in the cost function smooths the $\Delta\alpha$ map and therefore favors large objects. On the contrary, the passive illumination algorithm performs better for smaller objects since the algorithm assumes that the object size is negligible compared to the floor size, but its performance becomes significantly worse when the object gets large. Since we are considering large objects (e.g., humans in an office room) in general, the active illumination algorithm would be more useful in practice.

Effect of illumination change: The experimental results in Fig. 3-6 (a) and Fig. 3-7 (b) suggest that the active illumination algorithm is robust under illumination change while the passive illumination algorithm is not. This is consistent with the assumptions used to derive each algorithm. The passive illumination algorithm assumes that the change in the sensor reading is only due to the arrival of an object and does not account for the possibility of illumination change between the empty and occupied room states. The active illumination algorithm, however, only needs to compute the change in the light transport matrix between the empty and occupied room states. The light transport matrix is determined by room geometry, sensor and source placements and floor albedo distribution, and is unaffected by ambient light. The estimation of a light transport matrix too is unaffected by ambient light since it is based on measuring the *change* in sensor readings due to light modulation. The only crucial assumption needed for this to succeed is that the ambient light remains constant during the process of measuring a single light transport matrix, as discussed in Section 3.2.

Effect of noise: Experimental results in simulations (Fig. 3-6 (b)) and the real testbed (Fig. 3-7 (a)) suggest that the passive illumination algorithm is more sensitive

to noise than the active illumination algorithm. In passive illumination, Eq. (2.6) is based on the ratio of changes in the sensor readings. The sensor reading changes can be small, depending on the object size and location; taking a ratio of changes can magnify the error. In active illumination, the parameter σ can be adjusted to adapt to noise. We observed in our **MATLAB** simulations that the best σ is larger when the noise standard deviation gets larger. By adding more weight to the l_2 penalty term, the active illumination algorithm makes the optimal $\Delta\alpha^*$ smoother and adapts to a higher level of noise.

Limitations: So far, our study focused on localization of a single, static, flat rectangular object on an idealized small-scale testbed. However, real-world scenarios can be much more complicated, which often involves multiple moving objects with height (e.g., human occupants). In these scenarios, some of the assumptions of the light reflection model will be violated. Therefore, we expanded our testbed to room scale and generalized our algorithmic framework to handle such complex scenarios, which will be demonstrated in the following sections.

3.5 Localization of humans

3.5.1 Experimental setup

Encouraged by our initial success on the small-scale testbed with flat objects, we decided to move one step further and validate our localization algorithms on real human occupants. To achieve this, we worked with ECE Senior Design team *ActiLocate* in Fall 2017 and Spring 2018 semesters to build a new version of our testbed but at room scale. The overall block diagram of the room-scale testbed is shown in Fig. 3-8.

This testbed consists of the following components:

MSP432: A TI MSP432 microcontroller is used as the central controller of the

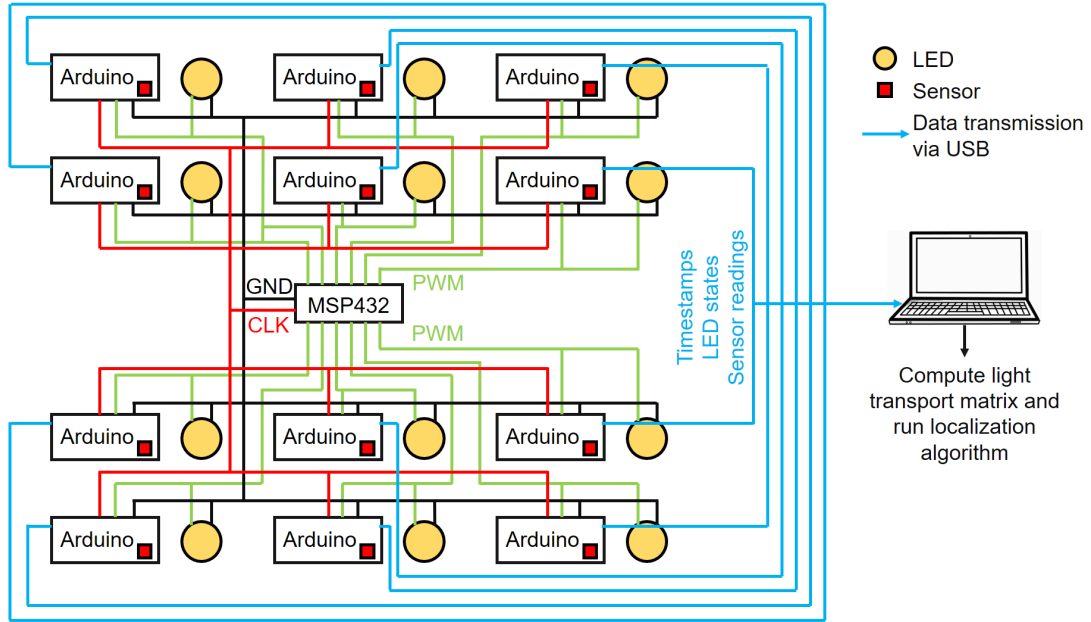

Figure 3-8: Block diagram of our room-scale testbed.

system. It sends out PWM signals to all the LED light sources to control their intensities so that the LEDs can illuminate as specified by a light state \mathbf{f} . It also sends a common clock signal (periodic square wave) to all sensor modules to ensure that they are synchronized. At each rising edge of the clock signal, the PWM signals will switch to the next light state in the light pattern stored in MSP432’s memory. In addition, it provides a common ground for all LEDs and sensor modules to ensure that voltage differences across the system are consistent.

LED modules: There are 12 LEDs in our system, placed on the ceiling on a 3×4 grid. Each LED is powered by a 12V DC wall power adapter and produces a maximum of around 800 lumens of light. The light is of warm color that is comfortable to the eyes of occupants. The LED states are controlled by the PWM signals *via* MOSFET transistors and they are on when their corresponding PWM signals are at high level.

Sensor modules: There are 12 sensor modules placed in pairs with the LEDs. Each sensor module has a microcontroller (Arduino Uno R3 board), an Adafruit TCS34725

single-pixel RGBC sensor and a USB port. The Arduino receives the clock signal from the MSP, the PWM signal of its paired LED, and power from a USB cable. When it is turned on, it sets its timestamp value to 0. At each rising edge of the clock signal, the Arduino polls its sensor to get the readings, determines the state of its paired LED *via* PWM, and increases its timestamp value by 1. Then, it sends the sensor readings, the LED state and the timestamp over the USB cables to a computer and waits until the next clock rising edge. To ensure synchronization, all Arduinos should be turned on before the MSP432 starts to generate clock signals so that their timestamps are uniform. (There is a switch that controls the MSP to start/stop generating clock signals.)

Computer: A computer is used to compute the light transport matrix and run the localization algorithm. It groups sensor readings and their corresponding light states according to timestamp values. It also stores the same light pattern as stored in the MSP432. For each timestamp, it compares the received light state vector (states of all 12 LEDs) with the light states in the stored light pattern to determine the state number. Once it receives data from a complete cycle through the light pattern, it will compute the light transport matrix following the procedure described in Section 3.2. Then, the obtained light transport matrix will be stored for pre-processing (e.g., averaging to reduce noise) before running the localization algorithm.

We marked a rectangular area of size 2.8m×2m on the floor as the test area. Inside the test area, we marked 63 ground truth locations with a blue masking tape on a 9 × 7 grid, with 25cm spacing. When collecting data, a person will stand on one of these ground truth locations such that the masking tape is in the middle between his/her feet. Fig. 3-9 shows two views of our new testbed.

For more idealized experimental validation, we also built a simulated room in Unity3D for data collection. We created a room in Unity3D with tables, doors and

Figure 3-9: Two views of our new room-scale testbed.

a screen as furniture, and a window that allows simulated sunlight to illuminate the interior. The dimensions of the room and the placement of furniture are chosen to best approximate our real testbed room. Compared with earlier Unity3D simulations in Sections 2.3.2 and 3.4.1, our new simulated room takes shadows and reflections from walls and furniture into account, which is more realistic. The test area and the ground truth locations in the simulated room are also identical to those in our testbed. To capture the body shape of an occupant more realistically, we used 8 human avatars that differ in height, size, gender and clothing. All human avatars are in a standing pose. Our simulated room and 8 human avatars are shown in Fig. 3-10.

3.5.2 Simulation and testbed experiments

We collected datasets in both Unity3D and the room-scale testbed with avatars and humans, respectively. In Unity3D, the ground-truth location of a human avatar is the projection of its geometric centroid onto the floor. When placing an avatar at each ground truth location on the grid, we rotated it around the vertical axis by an angle

Figure 3-10: A view of the simulated room in Unity3D with test area shown (up) and 8 human avatars used in data collection (down).

randomly chosen in range $[0^\circ, 360^\circ]$ to change its orientation. We followed the steps described in Section 3.2 to modulate the LEDs and obtain a light transport matrix A per avatar and ground truth location. In total, we obtained $63 \times 8 = 504$ light transport matrices. We also collected a light transport matrix A_0 for the empty room so that we can obtain the change ΔA .

We applied our localized ridge regression algorithm directly to the dataset collected with human avatars, although the algorithm assumes that objects are flat and Lambertian. Fig. 3-11 shows the average localization errors of our algorithm on each

human avatar. The average localization errors of human avatars all lie in the range

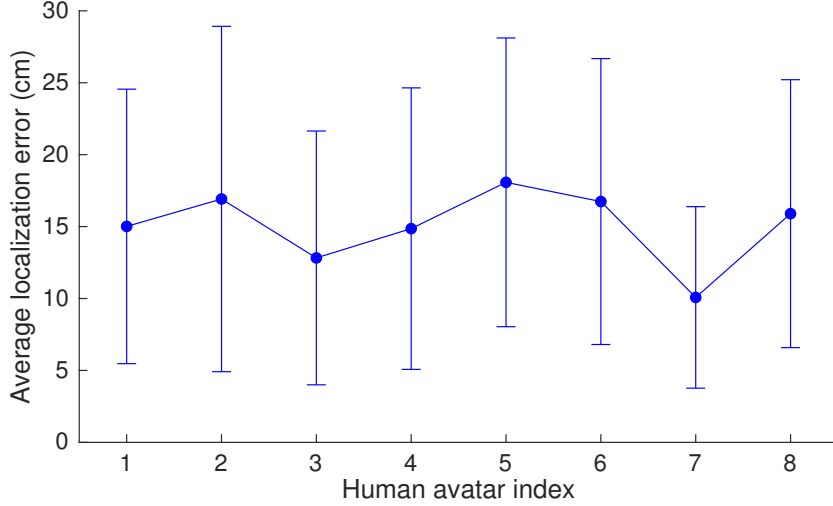

Figure 3-11: Mean and standard deviation of localization errors of the localized ridge regression algorithm for all human avatars across 63 ground-truth locations in Unity3D simulation.

[10cm, 20cm], which is smaller than the grid spacing of ground truth locations (25cm). Although the relative error with respect to the room size is significantly larger than simulations with flat objects, this is good performance considering that the flat object assumption is violated (shadows and complicated light reflection fields). It also suggests that modeling the object as albedo change is a good approximation even for objects with height.

In the room-scale testbed, we also collected a dataset with 8 different people. For each person, we turned on the MSP432 to start modulating LEDs and asked him/her to walk through all ground-truth locations following a zig-zag path. Each person was asked to stand still at each location for 5 modulation cycles through the light pattern before he/she moves to the next location. The obtained 5 light transport matrices for each location were then averaged to reduce noise. Before collecting data, we ran the system for several modulation cycles in empty state and averaged the obtained light transport matrices to obtain A_0 . Similarly, we applied the localized ridge regression

algorithm to the obtained data.

The average localization error of each person on the real testbed is shown in Fig. 3-12. The errors lie in range [15cm, 30cm] except for one outlier (person index 7) due to a bright interfering light source during data collection. Although more environmental noise, indirect light and interference exist in the testbed than in Unity3D simulation, the localization errors are only slightly larger than those in simulations (except person #7), which indicates that our algorithm is largely robust to real-world non-idealities, where assumptions about the object are violated.

Figure 3-12: Mean and standard deviation of localization errors of the localized ridge regression algorithm for all persons across 63 ground-truth locations on the room-scale testbed.

3.6 3D, moving and multiple object localization

3.6.1 Shadow-based 3D object localization

Modeling a 3D object with height (e.g., human) is more complicated than a flat object since a 3D object can cast shadows and bring complicated reflections due to its shape. To better localize a 3D object, we revised the light reflection model and modified our

localized ridge regression algorithm. We started from the simplest case by making the assumption that light reflected by the object surfaces is negligible. In this way, we only need to consider shadows caused by blocked light rays.

We assume that all light sources are point sources (negligible area). A shadow² is an area on the floor where light from the source is blocked by the object, and thus can be considered as an area with zero albedo. Therefore, we can estimate a shadow by estimating and thresholding the albedo change map. Light sources at different positions cast different shadows, and the idea of the shadow-based algorithm is to first estimate shadows from each light source, and then intersect them to obtain the area under the bottom of the object.

To estimate the shadow cast by light source j , we solve the following optimization problem

$$\Delta\boldsymbol{\alpha}_j^* = \arg \min_{\Delta\boldsymbol{\alpha}_j} \left[\|\Delta\mathbf{A}_j - \delta^2 C_j \Delta\boldsymbol{\alpha}_j\|_{l_2}^2 + \sigma_1 \delta^2 \|\Delta\boldsymbol{\alpha}_j\|_{l_2}^2 \right], \quad (3.17)$$

where $\Delta\boldsymbol{\alpha}_j$ is the albedo change resulting from the shadow of light source j , $\Delta\mathbf{A}_j$ is the column of light transport matrix change ΔA corresponding to source j , C_j consists of rows of matrix C corresponding to pairs between source j and all sensors. This problem is similar to Eq. (3.14) except that $\Delta\mathbf{A}_j$ and C_j are subvectors/matrices of $\Delta\mathbf{A}$ and C respectively. After estimating $\Delta\mathbf{A}_j$, we threshold it to obtain the estimated shadow of source j :

$$\mathcal{Q}_j = \left\{ (x, y) : \frac{\Delta\boldsymbol{\alpha}_j^*(x, y)}{\max_{(x, y)} |\Delta\boldsymbol{\alpha}_j^*(x, y)|} \leq -\tau \right\}. \quad (3.18)$$

We select points where the albedo change is smaller than or equal to a negative threshold since the albedo change caused by a shadow should always be negative. After estimating shadows from all light sources, we intersect them to obtain an area

²In this section, the shadow includes the area under the bottom of the object.

which should ideally be the area under the bottom of the object:

$$\mathcal{Q} = \{(x, y) : (x, y) \in \mathcal{Q}_j, \forall j\}. \quad (3.19)$$

To refine the localization result, we estimate the albedo change again within set \mathcal{Q} , similar to Eq. (3.16):

$$\begin{aligned} \Delta\boldsymbol{\alpha}^* &= \arg \min_{\Delta\boldsymbol{\alpha}} \left[\|\Delta\mathbf{A} - \delta^2 C \Delta\boldsymbol{\alpha}\|_{l_2}^2 + \sigma_2 \delta^2 \|\Delta\boldsymbol{\alpha}\|_{l_2}^2 \right] \\ \text{s.t. } \Delta\boldsymbol{\alpha}(x, y) &= 0, \quad \forall (x, y) \notin \mathcal{Q} \end{aligned} \quad (3.20)$$

After obtaining the optimal solution $\Delta\boldsymbol{\alpha}^*$, we use the centroid of $|\Delta\boldsymbol{\alpha}^*|$ as the final location estimate. σ_1 , τ and σ_2 are three parameters of this algorithm, which we optimize using a two-step grid search. We first search on a coarse grid and find the optimal set of parameters (which minimized the average localization error), and then search again on a finer grid centered at the optimal set of parameters found in the first step. In this way, we can greatly reduce the complexity of searching for the best parameters on a 3-dimensional grid.

We first tested our shadow-based localization algorithm in MATLAB simulation. We used the room size and source/sensor locations described in Section 2.3.1. We tested with cuboid objects, whose bottom areas have the same size as the flat objects (Table 2.1) and heights are chosen from 0%, 25%, 50% and 75% of room height. We set the albedo of the object surfaces to zero so that they do not reflect any light.

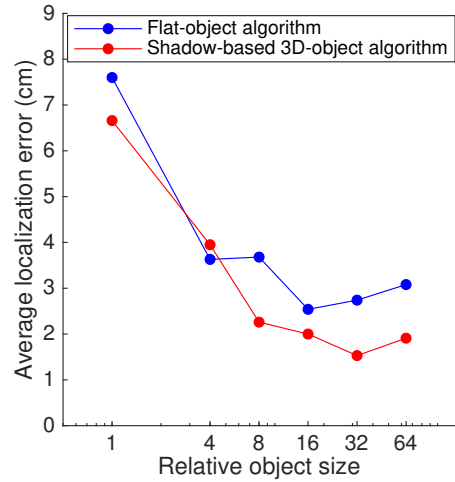

Fig. 3-13 shows the average localization errors of the localized ridge regression algorithm and the new shadow-based localization algorithm for each object bottom size and height. It can be seen from Fig. 3-13 that the localized ridge regression algorithm performs better for flat objects, while the shadow-based algorithm is better for 3D objects with large sizes, where the effect of shadows is more dominant. However, the improvement is quite limited since the second step (constrained $\Delta\boldsymbol{\alpha}$ estimation

inside set \mathcal{Q}) of the two algorithms is common; the only difference is the way they choose the region of interest \mathcal{Q} . Also, they both have tuning parameters which allow them to adapt to certain level of discrepancies between modeling assumptions and the actual environment (simulated or real).

We then tested the algorithms on the datasets collected with avatars and humans in Unity3D simulation and the room-scale testbed, respectively (Section 3.5.2), and the results are shown in Fig. 3.14. In Unity3D simulations, the shadow-based algorithm performs slightly worse than the localized ridge regression algorithm for all avatars. On the real testbed, the performances of the two algorithms are pretty close except some improvements on person #1 and #7. The assumption about negligible reflected light by objects no longer holds in these scenarios, as some humans or avatars wear bright clothes. The experimental results in Fig. 3.14 suggest that using the localized ridge regression algorithm is good enough for localization of humans, although the shadow-based algorithm is more principled.

Figure 3-14: Average localization errors of the flat-object (localized ridge regression) algorithm and the shadow-based 3D-object algorithm for avatars and humans in Unity3D simulation and the room-scale testbed, respectively.

3.6.2 Moving object localization

We also considered the case of a moving object. For a moving object, there are two ways of computing the change of a light transport matrix: one way is to subtract matrix A_0 for the background (empty room) from the matrix A for the current state; the other way is to take the difference between matrices A at time instants separated by k : $\Delta A(t_n) = A(t_n) - A(t_{n-k})$. In the latter way, we do not need to measure the matrix A_0 as the background; the change in the light transport matrix between frames is caused by the motion of the object. However, it may suffer from low signal-to-noise ratio since the change of A between frames is relatively small. Also, the object may become part of background when it stops moving. A sample localization using ΔA obtained *via* frame differencing is shown in Fig. 3-15.

Figure 3-15: Sample estimated albedo change map and location using ΔA obtained *via* frame differencing.

To test the effectiveness of these two approaches for a moving object, we collected light transport matrices corresponding to an empty room and a person walking along a trajectory in the room-scale testbed (Fig. 3-16). The trajectory connects 20 out of the 63 ground-truth locations, as shown in Fig. 3-17. At each ground-truth location on the trajectory, the person stops for several modulation cycles before walking to the next location. To reduce noise, we use the mean of the 3 most recent light transport

Figure 3-16: Side view when collecting data for empty room (left) and a moving person (right).

matrices as the light transport matrix for the current frame, and subtract A_0 (which is also the mean of a few measurements) from it. Also for frame differencing, we calculate ΔA as follows:

$$\Delta A(t_n) = \text{mean}(A(t_n), A(t_{n-1}), A(t_{n-2})) - \text{mean}(A(t_{n-3}), A(t_{n-4}), A(t_{n-5})) \quad (3.21)$$

We ran the localized ridge regression algorithm on the obtained ΔA matrix for each frame. We formed the estimated trajectory by putting together the location estimates of each frame. Fig. 3-17 shows the ground-truth trajectory and the estimated trajectories using frame differencing and background subtraction, respectively. The locations estimated using frame differencing are almost random, since the change of the light transport matrix A between frames is relatively small and completely drowned in noise. On the other hand, the trajectory estimated using background

Figure 3-17: Ground-truth and estimated trajectories of a person walking through 20 locations on the floor in the room-scale testbed. ΔA matrices are obtained using frame differencing and background subtraction respectively. The person walks from the bottom-left corner of the floor to the top-right corner.

subtraction basically follows the ground-truth trajectory, with reasonable localization errors. The average localization error across all frames is 23.04cm. This suggests that a background (empty room) measurement is still needed even when we localize a moving object.

3.6.3 Multiple object localization

We assumed in Section 3.1 that the albedo change caused by appearance of an object should mostly be concentrated in one connected blob. In the case of multiple objects, we hold the same assumption, assuming that the albedo change should be concentrated in multiple blobs, one for each object. We slightly modified the localized ridge regression algorithm for multiple objects as follows: after thresholding the initial estimate $\Delta \alpha_0^*$ and obtaining the set \mathcal{Q} (Eq. (3.15)), we divide points in \mathcal{Q} into connected components, and each connected component is considered as an object unless it is too small. The second step is the same as Eq. (3.16), and the estimated location of each

object is the centroid of $\Delta\alpha^*$ inside each connected component. We tested multiple object localization with two human avatars in the Unity3D-simulated room described in Section 3.5.1. Two samples of the localization of two avatars at different distances are shown in Fig. 3-18. When two avatars are far enough from each other, the albedo

Figure 3-18: Two samples of the localization of two human avatars in Unity3D simulation. The algorithm will distinguish the two avatars only when they are far enough from each other.

change can be separated into two connected components; when they are close by, the two connected components will merge into one.

We also varied the distance between the two avatars from 40cm to 240cm. The localization error of each avatar with respect to the distance between them is shown in Fig. 3-19. When the distance between the avatars is below 160cm, the albedo changes caused by the two avatars are indistinguishable.

Figure 3-19: Localization errors of two human avatars with respect to the distance between them in Unity3D simulation.

3.7 Estimation of light contribution matrix C

In Section 3.1 we introduced the light contribution matrix C , which can be calculated from the knowledge of room geometry, light source and sensor positions, and light intensity distribution function $q(\cdot)$. However, such knowledge is not always available, as it takes a significant amount of effort to measure source/sensor locations in a certain coordinate system, and a Lux meter to measure the $q(\cdot)$ function. Also, these measurements can be inaccurate. In such cases, we seek to estimate the light contribution matrix C by first sampling measurements of C (for all source-sensor pairs) at a few locations on the floor, and then reconstructing the entire C matrix from the sampled measurements. We studied the effect of sampling density on both the reconstruction quality and the localization error.

3.7.1 Sampling of matrix C

A row of matrix C ($C(i, j; :, :)$) can be represented as a map of contributions of different parts of the floor to the amount of luminous flux from source j to sensor i (value $A(i, j)$). An example of $C(i, j; x, y)$ for a certain source-sensor pair (i, j) and

the magnitude of its 2D discrete Fourier transform are shown in Fig. 3-20. It can be seen from Fig. 3-20 that the map of $C(i, j; x, y)$ is smooth and most of its energy is concentrated at low frequencies.

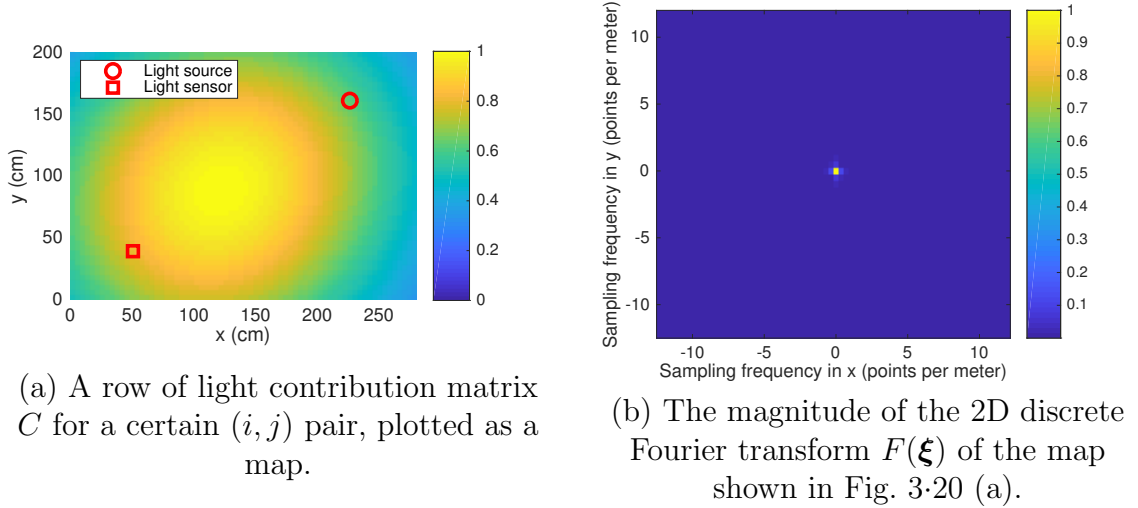

Figure 3-20: An example of a row of light contribution matrix C for a certain source-sensor pair (i, j) and the magnitude of its 2D discrete Fourier transform.

However, the signal $C(i, j; x, y)$ is not perfectly bandlimited, as the magnitudes of the high-frequency components in the Fourier transform are not perfectly zero. Therefore, no matter how densely we sample the signal $C(i, j; x, y)$, there will always be aliasing and the signal cannot be perfectly reconstructed. The sampling density is determined by how much aliasing we can tolerate during the sampling process. The sparser the sampling grid, the larger the aliasing as well as the reconstruction and localization errors. We determine the tolerance of aliasing by thresholding the magnitude of the Fourier transform (as a fraction of the magnitude of the zero-frequency component) and ignoring all frequency components below the threshold. After setting the tolerance threshold, we can then determine the sampling densities along x and y axes of the floor.

If we sample $C(i, j; x, y)$ with a series of impulses centered on a lattice Λ :

$$\tilde{C}(i, j; \mathbf{s}) = \sum_{\mathbf{w} \in \Lambda} C(i, j; \mathbf{s}) * \delta(\mathbf{s} - \mathbf{w}) \quad (3.22)$$

where \mathbf{s} and \mathbf{w} represent two-dimensional points in the spatial domain (floor), then the 2D Fourier transform of the sampled $\tilde{C}(i, j; \mathbf{s})$ will be the periodic sum of the Fourier transform of the original $C(i, j; \mathbf{s})$:

$$F_S(\boldsymbol{\xi}) = \sum_{\boldsymbol{\omega} \in \Gamma} F(\boldsymbol{\xi} - \boldsymbol{\omega}) \quad (3.23)$$

where Γ is the reciprocal lattice of Λ , and $\boldsymbol{\xi}$ and $\boldsymbol{\omega}$ represent two-dimensional points in the frequency domain. An example of a sampling of $C(i, j; x, y)$ and the magnitude of its 2D discrete Fourier transform are shown in Fig. 3-21.

Figure 3-21: An example of a sampling of $C(i, j; x, y)$ and the magnitude of its 2D Fourier transform.

By the Nyquist sampling theorem, we know that when the signal spectral support (set of frequencies with non-zero magnitudes in the Fourier transform) fits into a unit cell of the lattice Γ , the signal can be perfectly reconstructed from its samples.

Otherwise, there will be aliasing. Therefore, in choosing the reciprocal lattice Γ (which determines the sampling lattice Λ), we must ensure that the horizontal and vertical spacing of Γ are sufficiently large such that there is no overlap between the shifted copies of Fourier transform of the original $C(i, j; x, y)$.

Usually the high-frequency components of the Fourier transform of $C(i, j; x, y)$ are not perfectly zero. Therefore, we threshold the magnitude of the Fourier transform by a value T and obtain a supporting set $\Omega(i, j)$:

$$\Omega(i, j) = \left\{ \boldsymbol{\xi} : \frac{|F(\boldsymbol{\xi})|}{\max_{\boldsymbol{\xi}} |F(\boldsymbol{\xi})|} \geq T \right\} \quad (3.24)$$

where T is usually a small positive value close to zero. We ignore all frequency components outside $\Omega(i, j)$. Then, we take the union of $\Omega(i, j)$'s for all (i, j) pairs:

$$\Omega = \bigcup_{(i,j)} \Omega(i, j). \quad (3.25)$$

The set Ω determines the bandwidth (highest frequency component) of the Fourier transform in f_x and f_y axes. The reciprocal lattice Γ should ensure that there is no overlap between the shifted copies of Ω . We use two basis vectors parallel to x and y axes to define the lattice Γ , where

$$V_{\Gamma} = \begin{bmatrix} f_{Sx} & 0 \\ 0 & f_{Sy} \end{bmatrix} \quad (3.26)$$

is the sampling matrix of Γ . Then, the minimum sampling frequencies in f_x and f_y axes should satisfy:

$$f_{Sx} \geq 2B_x, f_{Sy} \geq 2B_y \quad (3.27)$$

where B_x and B_y are the bandwidth of set Ω in f_x and f_y axes, respectively. We take the equal sign in Eq. (3.27) and calculate the sampling matrix V_{Λ} of lattice Λ as

follows:

$$V_\Lambda = \begin{bmatrix} d_x & 0 \\ 0 & d_y \end{bmatrix} = V_\Gamma^{-1} \quad (3.28)$$

where d_x and d_y are the maximum sampling intervals in x and y axes, respectively. We can tell from Eq. (3.24)-(3.28) that d_x and d_y (and therefore Λ) are determined by the threshold T in Eq. (3.24). The higher the threshold T , the smaller the bandwidths B_x and B_y and the larger the sampling intervals d_x and d_y .

Once we determine the sampling intervals, the question left is how we should sample $C(i, j; x, y)$ values at points $(x, y) \in \Lambda$. Ideally we could do the following: if we have a flat object of negligible size, we can collect two light transport matrices: A_0 for the empty room and A when the object is placed at location (x, y) . Then, the only albedo change happens at (x, y) . By Eq. (3.6), we have:

$$\begin{aligned} \Delta A(i, j) &= A(i, j) - A_0(i, j) = \int_0^W \int_0^L C(i, j; x, y) \Delta\alpha(x, y) dx dy \\ &= C(i, j; x, y) \cdot \Delta\alpha(x, y) \cdot S \end{aligned} \quad (3.29)$$

where S is the area of the object. Then, $C(i, j; x, y)$ can be calculated using the following equation:

$$C(i, j; x, y) = \frac{\Delta A(i, j)}{\Delta\alpha(x, y) \cdot S}. \quad (3.30)$$

We can obtain the matrix ΔA by placing two objects with the same shape and known (but different) albedos at the same location (x, y) on the floor and taking the difference of the light transport matrices. In this way, $\Delta\alpha(x, y)$ is known and S can be calculated if the objects have a regular shape. Then, using Eq. (3.30), we can obtain samples of $C(i, j; x, y)$ on a lattice Λ . In practice, we cannot sample $C(i, j; x, y)$ with an object of negligible size since $\Delta A(i, j)$ would be so small that it would have been

drowned in noise. Instead, we used the 32x object (Table 2.1) for sampling and the value obtained using Eq. (3.30) to approximate the $C(i, j; x, y)$ value at the center of the object. The starting point of the sampling lattice Λ is $(x_0, y_0) = (\frac{L_{\text{obj}}}{2}, \frac{W_{\text{obj}}}{2})$ where L_{obj} and W_{obj} are the length and width of the sampling object, so that the object is at a corner of the floor and its boundaries overlap with the floor boundaries.

3.7.2 Estimating C from samples on a lattice

After obtaining samples of $C(i, j; x, y)$ on a lattice Λ which satisfies the Nyquist sampling theorem, we can recover the $C(i, j; x, y)$ map for all (x, y) locations. In this section, we present three methods to estimate $C(i, j; x, y)$ from samples on a lattice.

Inverse Fourier transform: The most straightforward way to obtain the signal $C(i, j; \mathbf{x})$ is to take the inverse Fourier transform of its Fourier transform $F(\boldsymbol{\xi})$. We can first compute the Fourier transform $F_S(\boldsymbol{\xi})$ of the sampled signal $\tilde{C}(i, j; \mathbf{x})$, and apply a low-pass filter to $F_S(\boldsymbol{\xi})$ to obtain $F(\boldsymbol{\xi})$ if there is no aliasing. We define a low-pass filter using the set Ω in Eq. (3.25):

$$\mathbf{1}_\Omega(\boldsymbol{\xi}) = \begin{cases} 1, & \text{if } \boldsymbol{\xi} \in \Omega \\ 0, & \text{otherwise} \end{cases} \quad (3.31)$$

Then, the original signal $C(i, j; \mathbf{x})$ can be obtained by taking the inverse Fourier transform of $F_S(\boldsymbol{\xi}) \cdot \mathbf{1}_\Omega(\boldsymbol{\xi})$:

$$\begin{aligned} \hat{C}(i, j; \mathbf{x}) &= IFT(F_S(\boldsymbol{\xi}) \cdot \mathbf{1}_\Omega(\boldsymbol{\xi})) \\ &= \sum_{\mathbf{s} \in \Lambda} |\Lambda| \cdot C(i, j; \mathbf{s}) \cdot \chi_\Omega(\mathbf{s} - \mathbf{x}) \end{aligned} \quad (3.32)$$

where $|\Lambda|$ is the determinant of Λ and

$$\chi_\Omega(\mathbf{x}) = IFT(\mathbf{1}_\Omega(\boldsymbol{\xi})) \quad (3.33)$$

Polynomial fitting: Another way to recover the $C(i, j; x, y)$ map is to fit a 2D polynomial of order N to the obtained samples:

$$\begin{aligned}\widehat{C}(i, j; x, y) &= \sum_{n=0}^N \left(\sum_{i=0}^n \beta(n, i) x^{n-i} y^i \right) \\ &= \boldsymbol{\beta} \cdot \mathbf{v}(x, y)\end{aligned}\tag{3.34}$$

where $\boldsymbol{\beta}$ is a vector of coefficients $\beta(n, i)$ of all polynomials, and $\mathbf{v}(x, y)$ is a vector of all polynomial values for some (x, y) . We then use the least squares fitting to obtain the coefficients that minimize the error:

$$\boldsymbol{\beta}^* = \arg \min_{\boldsymbol{\beta}} \|\mathbf{C}_{ij} - V \cdot \boldsymbol{\beta}\|_{l_2}^2\tag{3.35}$$

where

$$\mathbf{C}_{ij} = \begin{bmatrix} C(i, j; x_1, y_1) \\ \vdots \\ C(i, j; x_n, y_n) \end{bmatrix}, V = \begin{bmatrix} \mathbf{v}'(x_1, y_1) \\ \vdots \\ \mathbf{v}'(x_n, y_n) \end{bmatrix}\tag{3.36}$$

and $(x_1, y_1), \dots, (x_n, y_n)$ are points on the lattice Λ . When the number of points on the lattice Λ is greater than or equal to the number of polynomial coefficients, the problem (3.35) has a unique solution. Otherwise, we can make the solution unique by adding a regularization term (e.g squared l_2 norm of $\boldsymbol{\beta}$) with a small weight.

We evaluate the quality of reconstruction using the R^2 value, a metric commonly used to evaluate how well the data fits into a regression curve. We did not choose the mean squared error (MSE) as the metric since there is an unknown scaling factor in the expression of $C(i, j; x, y)$ which is determined by the maximum light source intensity and the area of the sensors. Instead, R^2 is normalized (with a maximum of 1), which makes it easier to see how much variation in the data is explained by the

fitted curve. The expression of R^2 is as follows:

$$R^2 = \frac{\sum_i (C(i, j; x_i, y_i) - \bar{C}(i, j; x_i, y_i))^2 - \sum_i (C(i, j; x_i, y_i) - \hat{C}(i, j; x_i, y_i))^2}{\sum_i (C(i, j; x_i, y_i) - \bar{C}(i, j; x_i, y_i))^2} \quad (3.37)$$

where (x_i, y_i) represents all points on the discretized floor grid with spacing δ (**not** on the lattice Λ) and $\bar{C}(i, j; x_i, y_i)$ is the mean of all $C(i, j; x_i, y_i)$ values. We estimated $C(i, j; x, y)$ with polynomials of order from 2 to 4 and sampling lattices Λ obtained by setting thresholds $T = 0.01, 0.05, 0.1$ in Eq. (3.24) in MATLAB simulation. The mean of R^2 values among all (i, j) pairs for different polynomial orders and thresholds are shown in Table 3.1.

Table 3.1: Mean of R^2 values among all (i, j) pairs for different polynomial orders and thresholds using polynomial fitting. $C(i, j; x, y)$'s are estimated from perfect samples (sampled with object of negligible size).

T	0.01	0.05	0.1
polynomial order = 2	0.9471	0.8765	0.8434
polynomial order = 3	0.9850	0.9450	0.9323
polynomial order = 4	0.9984	0.9919	0.9910

Table 3.1 suggests that approximating $C(i, j; x, y)$ using a polynomial of order 4 achieves good quality for certain thresholds T . We will use order 4 for polynomial fitting in subsequent experiments.

Model fitting: The most principled way to estimate $C(i, j; x, y)$ is to fit the sampled values with its expression derived from the light reflection model (Eq. (3.4)). Although we have no knowledge about room dimensions and light source and sensor locations, we can estimate them if the expression of $C(i, j; x, y)$ is known. For simplicity, we assume that the light sources are omnidirectional, i.e. $q(\beta) = 1$ for all β .

Then, we can rewrite the expression for $C(i, j; x, y)$ as follows:

$$C(i, j; x, y) = \frac{aH^3}{((x - X_j)^2 + (y - Y_j)^2 + H^2)^{3/2}((x - X_i)^2 + (y - Y_i)^2 + H^2)^2} \quad (3.38)$$

where H is the height of the room, a is some constant factor and (X_j, Y_j, H) and (X_i, Y_i, H) are the coordinates of source j and sensor i , respectively. All these variables are unknown and we wish to estimate them such that the expression best fits the sampled measurements. We did not achieve this by minimizing the MSE between sampled measurements and values of Eq. (3.38) at sampling locations, since the constant factor a has a much larger impact on the error than other unknowns. Instead, we maximize the cosine similarity between them. Define a function g :

$$g(X_j, Y_j, X_i, Y_i, H; x, y) = \frac{H^3}{((x - X_j)^2 + (y - Y_j)^2 + H^2)^{3/2}((x - X_i)^2 + (y - Y_i)^2 + H^2)^2} \quad (3.39)$$

Then, the goal is to estimate X_j, Y_j, X_i, Y_i and H such that $g(X_j, Y_j, X_i, Y_i, H; x, y)$ and $C(i, j; x, y)$ differ at most by a constant factor. To achieve this, we wish to maximize the cosine similarity between them on the lattice Λ by minimizing the following cost function:

$$f_{ij} = -\log \left(\frac{\mathbf{C}_{ij} \cdot \mathbf{g}_{ij}}{\|\mathbf{C}_{ij}\|_{l_2} \|\mathbf{g}_{ij}\|_{l_2}} \right) \quad (3.40)$$

where

$$\mathbf{C}_{ij} = \begin{bmatrix} C(i, j; x_1, y_1) \\ \vdots \\ C(i, j; x_n, y_n) \end{bmatrix}, \mathbf{g}_{ij} = \begin{bmatrix} g(X_j, Y_j, X_i, Y_i, H; x_1, y_1) \\ \vdots \\ g(X_j, Y_j, X_i, Y_i, H; x_n, y_n) \end{bmatrix} \quad (3.41)$$

and $(x_1, y_1), \dots, (x_n, y_n)$ are points on the lattice Λ . We minimize f_{ij} using a gradient descent algorithm. The purpose of taking the logarithm of cosine similarity between \mathbf{C}_{ij} and \mathbf{g}_{ij} is to make calculation of gradients $(\frac{\partial f_{ij}}{\partial X_j}, \frac{\partial f_{ij}}{\partial Y_j}, \frac{\partial f_{ij}}{\partial X_i}, \frac{\partial f_{ij}}{\partial Y_i}$ and $\frac{\partial f_{ij}}{\partial H})$ easier.

After obtaining the optimal values $X_j^*, Y_j^*, X_i^*, Y_i^*, H^*$ and the optimal \mathbf{g}_{ij}^* , the constant multiplier a in Eq. (3.38) can be calculated by minimizing the error $\|\mathbf{C}_{ij} - a\mathbf{g}_{ij}^*\|_{l_2}^2$. This will give a closed-form solution:

$$a^* = \frac{\mathbf{C}_{ij} \cdot \mathbf{g}_{ij}^*}{\mathbf{g}_{ij}^* \cdot \mathbf{g}_{ij}^*} \quad (3.42)$$

Then, all the unknowns in the expression of $C(i, j; x, y)$ (Eq. (3.38)) are estimated and we can calculate the values of $C(i, j; x, y)$ at all locations (x, y) on the floor.

3.7.3 Experimental results

We evaluated the performance of the three methods proposed in Section 3.7.2 through MATLAB simulation. The room dimensions and light source and sensor locations are the same as those of our room-scale testbed described in Section 3.5.1. As stated in Section 3.7.1, we sampled the $C(i, j; x, y)$ values with the 32x object (Table 2.1). We tested with sampling lattices Λ obtained by setting the threshold $T = 0.01, 0.02, 0.05, 0.1$ and 0.15 . The sampling intervals d_x, d_y and the number of points in the lattice Λ for different values of T are shown in Table 3.2.

Table 3.2: Sampling intervals along x and y axes (d_x, d_y) and number of points in the lattice Λ for different thresholds T when sampling with the 32x object.

T	d_x (cm)	d_y (cm)	Number of points in Λ
0.01	6.22	8.00	$41 \times 22 = 902$
0.02	14.74	18.18	$18 \times 10 = 180$
0.05	40.00	40.00	$7 \times 5 = 35$
0.1	56.00	66.67	$5 \times 3 = 15$
0.15	93.33	66.67	$3 \times 3 = 9$

For each threshold T (and sampling lattice Λ accordingly), we first computed the sampled values $C(i, j; x, y)$ for all (i, j) pairs and all (x, y) points in Λ using the procedure described in Section 3.5.1, and then applied the three proposed methods

to estimate the matrix C row by row. An example of original $C(i, j; x, y)$ (calculated using Eq.(3.4)) and the three estimated $\hat{C}(i, j; x, y)$'s for a certain (i, j) pair is shown in Fig. 3-22. It is clear from Fig. 3-22 that the $\hat{C}(i, j; x, y)$ map estimated with model fitting is the closest to the original $C(i, j; x, y)$.

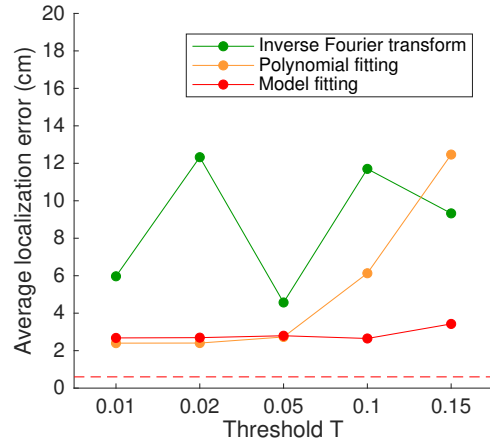

Figure 3-22: An example of original $C(i, j; x, y)$ and estimated $\hat{C}(i, j; x, y)$'s using three proposed methods in Section 3.7.2. The sampling lattice Λ is obtained by setting $T = 0.15$, which results in 9 sampling points.

Using the estimated \hat{C} matrices *via* the three methods, we ran the localized ridge regression algorithm to localize a flat rectangular object on the floor. Fig. 3-23 shows the average localization errors with respect to threshold T for estimated \hat{C} matrices

using the three methods, when localizing the 1x and 64x objects. The performance of the inverse Fourier transform method fluctuates due to boundary effects (sampling lattice Λ is finite, and for some choices of T there will be large margins that are not sampled); the polynomial fitting method performs well when $T \leq 0.05$, but its error increases significantly when T gets larger; the model fitting method performs consistently well for T values up to 0.15, when there are as few as 9 sampling points. This suggests that model fitting is the most robust method to sparse sampling, which is expected since we have knowledge of the model; the expression of the model is supposed to fit better to the sampled values than a polynomial or inverse Fourier transform.

(a) Errors when localizing the 1x object (Table 2.1).

(b) Errors when localizing the 64x object (Table 2.1).

Figure 3.23: Average localization errors with respect to the threshold T for original C and estimated \hat{C} matrices across 63 ground-truth locations in MATLAB simulation. Dashed lines indicate errors when using original C matrix calculated *via* Eq.(3.4) for localization.

We then tried to localize human avatars in Unity3D simulation using estimated \hat{C} matrices. We used the same simulated room and human avatars as described in Section 3.5.1, and also collected light transport matrices in Unity3D simulation with the

32x object when sampling $C(i, j; x, y)$ values. The average localization errors across all human avatars using original C and estimated \hat{C} matrices for different thresholds T are shown in Fig. 3-24. Although the estimated \hat{C} matrices using all three methods perform only slightly worse than the original C matrix, the model fitting method no longer outperforms the other two methods. Furniture and wall reflections can introduce errors in the sampling of $C(i, j; x, y)$ values; human avatars have complicated shapes and textures unlike flat objects; the objective function (Eq. (3.40)) for estimating the model parameters is non-convex, which makes model fitting sensitive to noise. All these factors affect the estimation quality of model fitting, causing it to perform not as well as in MATLAB simulations.

Figure 3-24: Average localization errors with respect to the threshold T for original C and estimated \hat{C} matrices across all human avatars in Unity3D simulation. Dashed line indicates error when using original C matrix for localization.

3.7.4 Conclusions

In this section, we proposed three ways to estimate the light contribution matrix C from a few samples when the parameters needed to compute C are not known. In

idealized MATLAB simulations, the C matrix estimated *via* model fitting achieves good accuracy with as few as 9 sampling points, which outperforms the other two methods since the sampled values of C are supposed to follow the expressions given by the model. In Unity3D simulations, the model fitting method with 9 sampling points performs only slightly worse than using the original C matrix, although it does not outperform the other two methods due to higher sensitivity to noise.

3.8 Localization with apertures on light sensors

In previous sections, we used single-pixel light sensors which output one intensity reading - the total luminous flux that is received by the sensor. However, when taking the sum of luminous fluxes from all incoming directions, the directional information of reflected light is lost. This information is very useful for localization since one can infer the object location from the directions of reflected light that is changed due to object appearance. In this section, we propose one way to separate received light according to incoming directions for more precise localization.

We achieve this by adding an aperture grid to each sensor. An aperture grid consists of a set of apertures which can be turned on or off to allow or block incoming light from certain directions and a cover which determines the sensor's field of view, as shown in Fig. 3-25. In practice, an aperture grid can be implemented using programmable liquid crystal devices. By modulating the aperture grid, we can obtain luminous flux intensities from multiple directions rather than a single aggregated intensity.

We modified our localized ridge regression algorithm as follows for localization with aperture grids on sensors. Instead of source-sensor pairs (i, j) , we consider pairs between a light source j and the k -th aperture of a sensor i , denoted as $((i, k), j)$. Under this setting, the light transport matrix and light contribution matrix become

Figure 3-25: Illustration of an aperture grid on a sensor.

$A((i, k), j)$ and $C((i, k), j; x, y)$, respectively, both with $N_s \times N_a$ rows where N_a is the number of apertures on each aperture grid. The expression of $C((i, k), j; x, y)$ becomes as follows:

$$C((i, k), j; x, y) = \begin{cases} \frac{I_{\max} S q(\beta_j) \cos \beta_j \cos^2 \theta_i}{16\pi^2 D_j^2 (H^2 + l_i^2)} & , \text{ if light ray from } (x, y) \text{ to} \\ & \text{sensor } i \text{ goes through} \\ & \text{aperture } k \\ 0 & , \text{ otherwise} \end{cases} \quad (3.43)$$

where β_j , D_j , θ_i and l_i are functions of x and y and are shown in Fig. 2-1, $q(\cdot)$ is the light intensity distribution function of the sources and H is the room height. The new light transport matrix $A((i, k), j)$ can be obtained by modulating both light sources and aperture grids following a similar procedure to the one in Section 3.2. After obtaining the new light transport matrix A (and therefore ΔA) and contribution matrix C , we use the same localized ridge regression algorithm as in Section 3.3.2 for localization. The optimal solution of $\Delta \alpha$ is expected to be more accurate since we now have N_a times the number of equations in problem (3.7).

We experimented in MATLAB simulation with the same room size and source/sensor

placements as our room-scale testbed (Section 3.5.1). We set the field of view of a sensor such that each sensor looks at an area of size $1.02\text{m} \times 0.78\text{m}$ on the floor (Fig. 3-26). This ensures that any point on the floor is in the field of view of at least

Figure 3-26: The area on the floor corresponding to a sensor and its apertures' field of view.

one sensor. Within a sensor's field of view, we divided the aperture grid into 1×1 , 2×2 , 3×3 and 4×4 apertures, and for each grid configuration, we localized the 1x, 4x, 16x and 64x objects (Table 2.1), each placed at 63 ground-truth locations. The average localization errors for different grid configurations and object sizes are shown in Fig. 3-27. We noticed that the average localization error decreases when we increase the number of apertures in each grid. This is expected since we have more information about incoming light. However, sensors with 1×1 and 2×2 aperture grids perform worse than sensors without aperture grids, since the aperture grids limit the sensors' field of view and any location on the floor is covered by fewer sensors.

Therefore, we increased the sensors' field of view by enlarging the size of the aperture grids. The increased field of view ensures that every sensor can see the entire floor (as in previous experiments when there is no aperture grid on sensors). This ensures that any location on the floor is seen by all sensors. When enlarging the aperture grid size, we keep the grid spacing unchanged and only extend apertures on

Figure 3·27: Average localization errors for different aperture grid configurations and object sizes. Dashed line indicates errors for sensors without aperture grids.

the boundaries of the grid, as illustrated in Fig. 3·28.

We repeated the MATLAB simulation experiments for enlarged aperture grids. The average localization errors for different grid configurations and object sizes are shown in Fig. 3·29. Compared with the performance of original grid size, the enlarged grid size performs much better.

We also compared the estimated albedo change maps for sensors without aperture grids and sensors with enlarged aperture grids (Fig. 3·30). The albedo change estimate is more accurate (closer to the true shape of the object) when 3×3 aperture grids are applied to sensors.

3.9 Summary

In this chapter, we proposed localization algorithms based on the active illumination methodology. Using the relationship between modulated light source intensities and single-pixel sensor responses, described as the light transport matrix A , the active illumination methodology is theoretically more robust to ambient illumination changes than passive illumination. We proposed two variants of localization algorithms, namely LASSO and localized ridge regression, where the latter has a better performance overall. In simulated (MATLAB and Unity3D) experiments, we demonstrated that the localized ridge regression algorithm is as accurate as passive illumination when localizing flat objects, but it is significantly more robust to sensor noise and ambient illumination changes than passive illumination. In the real testbed, the localized ridge regression algorithm performs much better than passive illumination due to higher robustness to noise. We also demonstrated *via* Unity3D simulations and our room-scale testbed that the localized ridge regression algorithm is still accurate when localizing human occupants, although the model assumes that objects should be flat.

Moving forward, we extended our framework to 3D, moving and multiple objects. We proposed a more principled shadow-based algorithm for 3D object localization, which is found to have similar performance to the localized ridge regression algorithm. For moving objects, the localized ridge regression algorithm works well when the change of light transport matrix ΔA is obtained by subtracting background (A_0) from current measurements (A). Multiple objects can be localized simultaneously by performing connected component detection on the estimated albedo change map, but objects can become indistinguishable when they get close to each other.

We also studied the problem of estimating the light contribution matrix C from samples when room dimensions and source/sensor locations are not available. We de-

terminated the sampling lattice *via* 2D Fourier spectrum analysis, and proposed three ways to estimate matrix C - inverse Fourier transform, polynomial fitting and model fitting. The model fitting approach is the most principled since it fits the expression of C into the obtained samples, and it does perform the best in MATLAB simulations, especially when there are very few sampling points. However, in the Unity3D-simulated room with human avatars, it does not outperform the other two approaches as it is more sensitive to sampling noise.

Finally, we proposed a new sensor design using aperture grids. By separating incoming luminous flux according to directions, we can obtain directional information about light that has changed due to object appearance. As a result, the localization accuracy is improved and the estimated albedo changes are more accurate.

Chapter 4

Data-driven approaches to indoor localization *via* active scene illumination

In Chapter 3 we introduced our model-based localized ridge regression algorithm *via* active illumination, which can accurately localize a flat object or a human occupant. However, the model-based algorithm has strict modeling assumptions on the properties of the floor, walls or object, which are not always satisfied in practice. Such deviations from the modeling assumptions can decrease the algorithm’s performance. Also, the algorithm requires either knowledge of room dimensions, source/sensor locations and characteristics, or a set of sampled values of the light contribution matrix C , both of which cannot be obtained easily.

Therefore, in this chapter, we explored data-driven approaches to localization *via* active illumination, which require only a training dataset and a machine learning model. Modeling assumptions or knowledge of geometries are no longer required - all they require is a good training set that covers a wide variety of scenarios.

We use the change of light transport matrix between empty and occupied room states $\Delta A = A - A_0$ as the feature, and the object (or occupant) location (x, y) as the label. The estimations of location along x and y axes are considered as two regression problems. We will consider both classical data-driven approaches and neural networks.

4.1 Classical data-driven approaches

For classical data-driven approaches, we consider support vector regression (SVR) and K -nearest neighbor (K NN) regression. In these two approaches, we pre-process the input feature as follows - we first normalize the matrix ΔA by dividing all its entries by the magnitude of the entry with the largest absolute value:

$$\Delta A' = \frac{\Delta A}{\max_{i,j}(|\Delta A_{ij}|)} \quad (4.1)$$

such that all entries of $\Delta A'$ lie in the interval $[-1, 1]$; then, the flattened $\Delta A'$ matrix is used as the input feature vector to the models.

4.1.1 Support vector regression (SVR)

The support vector regression (SVR) is a variant of the support vector machine (SVM) for binary classification. In SVR, we wish to find a function that maps a feature vector \mathbf{x} to a real value:

$$f(\mathbf{x}) = \mathcal{K}(\boldsymbol{\beta}, \mathbf{x}) + b \quad (4.2)$$

where $\mathcal{K}(\cdot, \cdot) = \langle \phi(\cdot), \phi(\cdot) \rangle$ is a positive-definite and symmetric kernel, and b is a constant. Similar to classification SVM, we want to minimize the norm of $\boldsymbol{\beta}$:

$$\min \frac{1}{2} \|\boldsymbol{\beta}\|_{l_2}^2 \quad (4.3)$$

subject to the following constraints:

$$|y_i - \mathcal{K}(\boldsymbol{\beta}, \mathbf{x}) - b| \leq \epsilon, \forall i \quad (4.4)$$

where y_i is the label of the i -th training sample and ϵ is the tolerance of regression errors. Since there may not exist a vector $\boldsymbol{\beta}$ that satisfies all the constraints (4.4), we

form the following optimization problem by introducing slack variables ξ_i and ξ_i^* :

$$\begin{aligned}
& \min \frac{1}{2} \|\boldsymbol{\beta}\|_{l_2}^2 + B \sum_{i=1}^N (\xi_i + \xi_i^*) \\
& \text{subject to } y_i - \mathcal{K}(\boldsymbol{\beta}, \mathbf{x}) - b \leq \epsilon + \xi_i, \forall i \\
& \quad -y_i + \mathcal{K}(\boldsymbol{\beta}, \mathbf{x}) + b \leq \epsilon + \xi_i^*, \forall i \\
& \quad \xi_i \geq 0, \forall i \\
& \quad \xi_i^* \geq 0, \forall i
\end{aligned} \tag{4.5}$$

where N is the number of training samples and B is called the box constraint, which controls the trade-off between bias and variance. By solving the dual problem of problem (4.5), we obtain the optimal function to predict new values given feature vectors:

$$f^*(\mathbf{x}) = \sum_{i=1}^N (\alpha_i - \alpha_i^*) \mathcal{K}(\mathbf{x}_i, \mathbf{x}) + b \tag{4.6}$$

where α_i and α_i^* satisfy the following constraints:

$$\begin{aligned}
& \sum_{i=1}^N (\alpha_i - \alpha_i^*) = 0 \\
& 0 \leq \alpha_i \leq B, \forall i \\
& 0 \leq \alpha_i^* \leq B, \forall i
\end{aligned} \tag{4.7}$$

The training samples \mathbf{x}_i with regression error less than ϵ satisfy $\alpha_i = 0$ and $\alpha_i^* = 0$. If either $\alpha_i = 0$ or $\alpha_i^* = 0$ is not satisfied, the training sample is called a support vector, and only support vectors determine the predicted value of the regressor.

In our experiments, we trained two support vector regressors to estimate object location (\hat{x}, \hat{y}) along both axes. We used the radial basis function (RBF) as the kernel, and found the optimal parameters ϵ and B on a two-dimensional grid *via* a 5-fold cross-validation.

4.1.2 K -nearest neighbor (K NN) regression

In K NN regression, the predicted value of a feature vector is determined by the labels of its K nearest neighbors in the training set with the smallest distances to the feature vector. The choice of a distance metric in the feature-vector space may vary, and we chose Euclidean distance as the metric:

$$d(\mathbf{x}, \mathbf{x}_i) = \|\mathbf{x} - \mathbf{x}_i\|_{l_2} \quad (4.8)$$

The reason behind this choice is as follows. By Eq. (3.6), we have

$$\Delta A(i, j) = C(i, j; x, y) \cdot \Delta\alpha \cdot S \quad (4.9)$$

where (x, y) is the object location, when the object area $S \ll W \times L$. Since $C(i, j; x, y)$ is continuous and rather smooth (Fig. 3-20 (a)) for all (i, j) pairs, when the object is moved by a small distance, all the $\Delta A(i, j)$ values will change by a small amount; when the object movement is large, it is unlikely that the changes of $\Delta A(i, j)$ values for all (i, j) pairs will remain small, since sources and sensors are placed at different locations across the entire ceiling. Also, the effect of scaling by $\Delta\alpha \cdot S$ is eliminated since we have normalized ΔA (Eq. (4.1)). Therefore, a small distance in the feature-vector ($\Delta A'$) space corresponds to a small distance in the (x, y) space. One can also use $l_1, l_3, \dots, l_\infty$ distances instead of l_2 distance.

For a test sample, we first compute its distance to all data samples in the training set, and then sort the distances and find the K smallest ones. The predicted location of the test sample is given as the weighted centroid of the ground-truth locations of the K nearest neighbors:

$$\hat{x} = \sum_{i=1}^K w_i x_i, \hat{y} = \sum_{i=1}^K w_i y_i \quad (4.10)$$

where (x_i, y_i) is the ground-truth location of the i -th nearest neighbor, and the weights w_i are proportional to the reciprocal of the Euclidean distances:

$$w_i = \frac{1}{d(\mathbf{x}, \mathbf{x}_i)} \cdot \frac{1}{\sum_{i=1}^K \frac{1}{d(\mathbf{x}, \mathbf{x}_i)}}. \quad (4.11)$$

The parameter K is optimized through grid search and 5-fold cross-validation.

4.2 Convolutional neural network (CNN) approach

Besides classical data-driven approaches, we also consider CNN-based approaches. CNNs are popular for their good performance on image data, where they make use of spatial correlation between adjacent pixels in an image by applying convolutional kernels. Also, the number of parameters is greatly reduced compared with a fully-connected neural network, which makes training much faster and reduces overfitting.

Although our input feature $(\Delta A')$ is not a typical image, we can reshape it to make use of spatial correlation between sensors. We note that sensors closer to the occupant should have larger reading changes between empty and occupied room states than those further away. To leverage this spatial relationship, we reshape the $N_s \times N_f$ matrix $\Delta A'$ into a 3D tensor of N_f channels. Each channel consists of entries from one column of $\Delta A'$ corresponding to the contribution of light from a light source to all sensors, and is reshaped into a 2D matrix to match the spatial ordering of the actual sensor grid on the ceiling. This will allow the network to extract the occupant’s location from the channel images. Fig. 4-1 shows an example of the original $\Delta A'$ matrix and the reshaped 3D tensor.

We have 12 light sources and 12 sensors placed on a 3×4 grid in our room-scale testbed. Therefore, the reshaped input has 12 channels, and each channel contains a 3×4 “image” of light transport matrix changes. For this “image” size, the choice

Figure 4-1: Example of an original $\Delta A'$ matrix and its reshaped 3D tensor form. Red boxes correspond to the same entries. Occupant is located at the lower right corner of the floor.

of convolutional kernel and stride sizes is very limited. Therefore, to allow sub-pixel kernel and stride sizes, we upsample the channel “images” using bilinear interpolation with several upsampling factors.

We proposed a CNN with 4 layers: 2 convolutional layers, 1 hidden layer and 1 output layer. The first two convolutional layers have 32 and 64 output channels and use 2D convolutional kernels. The second convolutional layer is flattened and then fully connected with the hidden layer. The hidden layer is fully connected with the output layer which gives the estimated occupant location (\hat{x}, \hat{y}) . The kernel and stride sizes of the two convolutional layers and the dimension of the hidden layer are chosen according to the upsampling factor of the input (which determines the input size), that are listed in Table 4.1. The loss function is the mean squared localization error (squared Euclidean distance between estimated and ground truth locations). To avoid the problem of vanishing gradients, the outputs of the two convolutional layers and the hidden layer are activated by a LeakyReLU function with $\alpha = 0.1$. Figure

Table 4.1: Parameters of our proposed CNN for different upsampling factors.

Upsampling factor	1	3	5	10
Input channel size	3×4	7×10	11×16	21×31
Conv1 kernel size	2×2	4×4	4×4	6×6
Conv1 stride size	(1,1)	(1,1)	(2,2)	(2,2)
Conv2 kernel size	2×2	2×2	3×3	4×4
Conv2 stride size	(1,1)	(1,1)	(1,1)	(2,2)
Dimension of hidden layer	170	300	500	750

4.3 Experimental results

To validate and compare the performance of the classical data-driven approaches and our proposed CNN, we performed experiments in both Unity3D simulations with human avatars and our room-scale testbed with occupants. The experimental settings and data collection process are described in Section 3.5.1 and Section 3.5.2 respectively.

4.3.1 Simulation experiments

As stated in Section 3.5.2, we collected $63 \times 8 = 504$ data samples using 8 human avatars in Unity3D simulation. These samples are used as the test set. We collected another dataset for training using the same 8 avatars, each placed at 1,530 ground-truth locations on a 45×34 grid with 5cm spacing. There is no overlap between the training and test set grids.

We considered two different scenarios when training the classical data-driven models and our proposed CNN: private and public. In a private scenario, like a home, the system can only be used by a small set of people, and most of the time, the system will see users which it has encountered before. Therefore, we can train a model with data from all human avatars and test on the same avatars. In a public scenario, like a store, the model cannot be trained on all users since there can always be new users that have not been seen by the system. In this case, we have to train with data from all but one human avatar and test on the excluded avatar.

In the private scenario, out of $1,530 \times 8$ training samples we use only 50×8 samples (50 random samples for each avatar) for training. This is to simulate the real-world scenario when we have few training data. All the data-driven models are trained using the same set of samples. Then, we test each model on each avatar’s 63 test samples (with 25cm spacing) which are separate from the larger training set of 1530×8 samples. In the public scenario, we perform a leave-one-person-out cross-validation. We train a model on 7 avatars (50 samples per avatar) and test it on the eighth avatar, and repeat this process 8 times so that each of the avatars is left out for testing. The performance of a model is evaluated in terms of average localization error.

We tested several choices of the upsampling factor for the input tensor of our CNN: 1 (no upsampling), 3, 5 and 10. As the input size is scaled, we scale the network to roughly match the input size by changing the network parameters (Table 4.1). The

Table 4.2: Average localization errors of our proposed CNN for different upsampling factors in private and public scenarios in Unity3D simulation.

Upsampling factor	1	3	5	10
Average localization error - private (cm)	6.43	6.25	5.69	6.47
Average localization error - public (cm)	7.89	7.96	8.04	8.61

network parameters and average localization errors for different upsampling factors are shown in Table 4.2. The network with an upsampling factor of 5 performs best in the private scenario, while performing only slightly worse than the best case in the public scenario.

We compared the performance of SVR, *KNN* regression, our proposed CNN (with an upsampling factor of 5) and our model-based localized ridge regression algorithm (Section 3.3.2). Figure 4.3 shows the average localization errors for each human avatar for the four methods. The CNN approach outperforms the other three methods for all human avatars in both scenarios. It reduces the average localization error across all avatars by 47.69% and 46.99% in private and public scenarios, respectively, compared to the best-performing method among SVR, *KNN* and model-based.

Figure 4.3: Average localization errors for each human avatar for SVR, KNN regression, CNN and model-based (localized ridge regression) algorithms in Unity3D simulation. The model-based algorithm has the same errors in private and public scenarios since it does not need training.

4.3.2 Testbed experiments

We performed testbed experiments using the same dataset as we used in previous experiments (Section 3.5.2). We collected data for 8 human occupants, where each of them walked through 63 ground-truth locations on a 9×7 grid with 25cm spacing. We also considered both private and public scenarios in the testbed experiments. In the private scenario, we randomly selected 50 samples from each person to form the training set (totaling 400 samples), and used the remaining 13 samples of each person as the test set (totaling 104 samples). In the public scenario, we performed a leave-one-person-out cross-validation by training the models on 7 persons (using $63 \times 7 = 441$ samples) and testing on the eighth person (63 samples). The process was repeated 8 times so that each person is left out for testing.

We also compared the performance of the same 4 algorithms in private and public scenarios. For the CNN, we chose the network corresponding to the upsampling factor of 5. Figure 4-4 shows the average localization error for each person in both scenarios. Compared with the best-performing method (among SVR, KNN and model-based) in each scenario, our CNN reduces the average localization error across all individuals by 36.54% in the private scenario and by 11.46% in the public scenario.

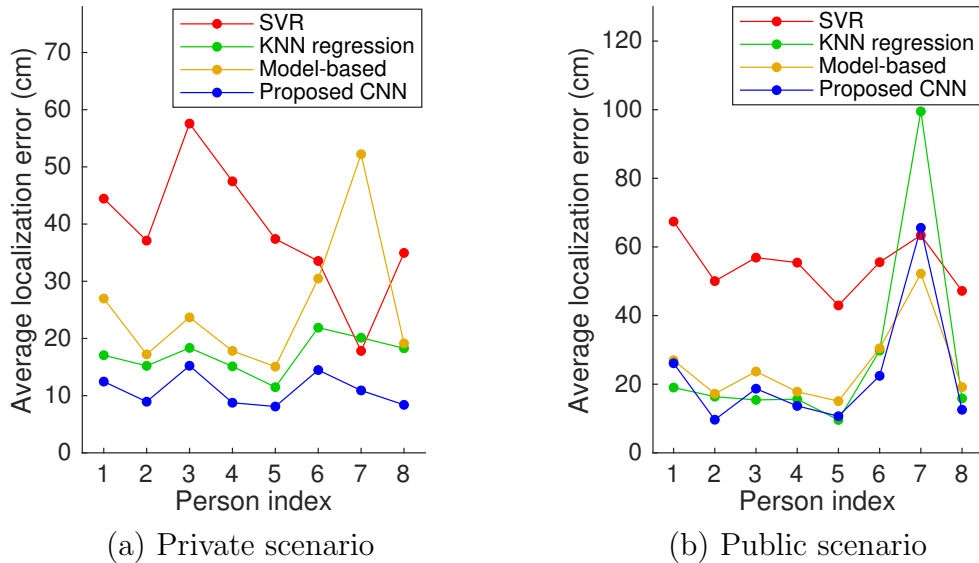

Figure 4-4: Average localization errors for each person for SVR, KNN regression, CNN and model-based (localized ridge regression) algorithms in the room-scale testbed.

4.4 Transfer learning

A popular way to improve the performance of deep neural networks is to use transfer learning. Transfer learning refers to the techniques of solving a new problem using knowledge learned from solving a different but related problem. It is found to be helpful when there is high correlation between the two problems, and especially when the training set for the new problem is small. In Section 4.3, we trained our local-

ization CNN with around 400 samples in both private and public scenarios, which is a very small training set, and therefore we seek to improve the performance of our CNN using transfer learning.

There are two stages in transfer learning: offline training and fine-tuning. In offline training, a neural network is trained from scratch with a large training set from one domain; and in the fine-tuning stage, another network is initialized using the weights of the pre-trained network, and then trained with a smaller training set from another domain.

In our experiments, we first pre-trained our localization CNN (with upsampling factor of 5) with the training samples collected in Unity3D simulation (Section 4.3.1). All the 1,530 samples from each of the 8 avatars are used for training, totaling 12,240 samples. Then, we used the samples collected in our testbed for fine-tuning, where we also consider private and public scenarios. During the fine-tuning stage, the parameters of the two convolutional layers are frozen, so that they become a feature extractor. Only the parameters for the hidden output layers are updated. The average localization errors for our CNN with and without transfer learning in private and public scenarios are shown in Fig. 4-5. In both scenarios, transfer learning did not significantly improve the performance of the CNN, and for some avatars it performs even slightly worse. The reason can be one of the following: either the datasets from two domains (Unity3D and testbed) are not similar enough, or the CNN trained with only testbed data is already close to optimal.

To figure out the reason why transfer learning does not improve performance, we conducted another set of experiments, where both training and fine-tuning sets are from Unity3D simulation. We collected the training set with a mannequin (human avatar without texture) of three different sizes: small, medium and large, which are scaled such that mannequin heights are equal to the minimum, average and maximum

Figure 4-5: Average localization errors for our CNN with and without transfer learning in private and public scenarios in the room-scale testbed. The training-and-test splits of data in both scenarios are the same as those in Section 4.3.2.

heights of the 8 human avatars. Fig. 4-6 shows the mannequin used in our experiments. Mannequin of each size is placed at the same 1,530 ground-truth locations as those in Section 4.3.1. We trained the CNN with $1,530 \times 3 = 4,590$ samples from the mannequin, and fine-tuned it with the same samples used to train the CNN for private and public scenarios in Section 4.3.1.

Fig. 4-7 shows a comparison of average localization errors with and without transfer learning in both scenarios. Even when the training and fine-tuning datasets are extremely similar, the fine-tuned CNN only reduces average localization error across all human avatars by 1.34% and 3.71% in private and public scenarios, respectively, compared with the CNN trained from scratch. This suggests that the CNN trained from scratch with the fine-tuning set (400 samples in private scenario, 350 in public scenario) is already close to its optimal, which is expected since the size and number of parameters of our CNN is small compared with the majority of CNNs.

Figure 4-6: The mannequin used in Unity3D simulation to collect training data.

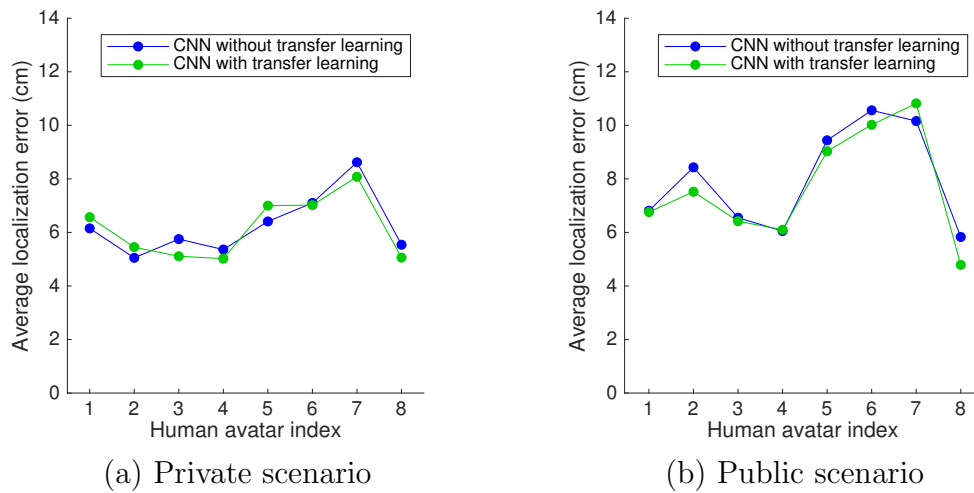

Figure 4-7: Average localization errors for our CNN with and without transfer learning in private and public scenarios in Unity3D simulation. In transfer learning, the CNN is pre-trained with data samples from the mannequin.

4.5 Robustness to sensor failures

In Chapter 3, we evaluated our algorithm’s robustness against noise and ambient illumination changes. Besides these non-idealities, failures of light sources or sensors can also happen and affect the algorithm’s performance. Light source failures can be easily detected by human eyes, as the failed light sources will stop illuminating; however, failures of light sensors are much harder to detect since they are not visible. In this section, we will test the robustness of our model-based localized ridge regression algorithm and our CNN against sensor failures.

We assume that a failed sensor will constantly output zero readings. To simulate sensor failure using already collected datasets, we first computed change of light transport matrix ΔA , and then set $\Delta A(i, j) = 0$ for all sources j and all failed sensor indexes i . The processed ΔA matrix is then fed into the model-based algorithm or the CNN as input.

We experimented with data from both Unity3D simulations and the room-scale testbed. We used the same datasets used in Section 3.5.2, each having $63 \times 8 = 504$ samples collected from 8 avatars/persons. We varied the number of failed sensors from 1 to 11. For each specified number of failed sensors N_{fail} , we randomly selected N_{fail} sensors out of N_s sensors, and set the corresponding ΔA entries to zero. This process was repeated 3 times and the localization errors from 3 repetitions were averaged. For the model-based algorithm, there are two options: after setting $\Delta A(i, j) = 0$ for failed sensors, we can either zero the rows of light contribution matrix C corresponding to failed sensors, as if the failed sensors do not exist; or we can just keep matrix C as it is. Also when testing the CNN, we divided the dataset into 3 folds, and for each N_{fail} and each repetition, we performed a 3-fold cross-validation and averaged the localization errors of all folds. Note that the data folds used for training do not take failed sensors into account; only failed sensor readings in the test fold are set to zero.

Figure 4-8: Average localization errors with respect to the number of failed sensors for the model-based algorithm and the CNN in Unity3D simulation and the testbed. Both options for the model-based algorithm are tested.

Fig. 4-8 shows the average localization error with respect to the number of failed sensors for model-based algorithm and CNN in Unity3D simulations and testbed. The localization errors for the model-based algorithm (if we choose to keep matrix C) and the CNN increase at similar rates as the number of failed sensors increases, and the model-based algorithm always has a higher error than the CNN. However, if we choose to zero the rows of C corresponding to failed sensors, the localization error for the model-based algorithm decreases significantly compared to the other two cases, and remains almost constant when $N_{fail} \leq 6$ in both Unity3D simulations and the testbed. This is to be expected since the model equation (Eq. (3.6)) is not violated when we completely remove a sensor and the corresponding rows of matrix C ; it is violated when we have wrong sensor readings.

4.6 Summary

In this chapter, we explored several data-driven approaches to localization *via* active scene illumination, including SVR, K NN regression and a proposed CNN model. Compared with model-based algorithms, data-driven approaches do not require any modeling assumptions or knowledge of room geometry and source/sensor characteristics. We compared the three data-driven approaches as well as the model-based localized ridge regression algorithm, and our proposed CNN outperforms all the other methods in private and public scenarios in both Unity3D simulations and the real testbed, with only around 400 training samples.

We also sought to improve the performance of our CNN using transfer learning. However, when we trained the CNN with a large Unity3D dataset and fine-tuned it with testbed data, there is no improvement compared with the CNN trained from scratch with only testbed data. The improvement is minimal even when we trained with data from a Unity3D mannequin and tested with Unity3D human avatars. This suggests that the CNN trained from scratch is already close to optimal since it is a small network.

Finally, we evaluated the robustness of the model-based algorithm and the CNN to sensor failures. The two approaches have similar error increases as the number of failed sensors increases, while the model-based algorithm has slightly higher errors. However, if we could detect the failed sensors and remove the corresponding entries of the light transport matrix A and rows of light contribution matrix C , the model-based algorithm will become much more robust to sensor failures and perform well even when half of the sensors have failed.

Chapter 5

Conclusions

5.1 Summary of the dissertation

This dissertation proposed an active illumination methodology which aims to accomplish three goals for an indoor occupant localization system: accuracy, robustness and privacy preservation. In our system, an array of single-pixel light sensors is used to preserve visual privacy of room occupants, while modulated LED light sources are used to improve the system's robustness to noise and illumination changes. To assure accurate localization, we explored and proposed both model-based and data-driven algorithms.

The model-based algorithm is derived under the assumption that both the floor and the object are Lambertian and flat. Using Lambert's Cosine Law, the model relates the change of light received by sensors to the change of floor albedo due to the presence of an object. Our proposed localized ridge regression algorithm estimates floor albedo change and object location based on the change of light transport matrix and parameters of the room and light sources/sensors. We demonstrated *via* simulation and testbed experiments that the proposed algorithm is more robust to noise and illumination changes than the model-based passive illumination algorithm, and more robust to sensor failures than data-driven approaches. The proposed algorithm can also accurately localize 3D (e.g., human occupants), moving and multiple objects under certain circumstances. Furthermore, we proposed ways to estimate the light contribution matrix C when information about room geometry and light

sources/sensors is not available, and a sensor design with aperture grids which improves localization accuracy.

On the other hand, we also explored data-driven approaches that do not require modeling assumptions or room, source or sensor parameters. We proposed a convolutional neural network (CNN) for localization, where we reshaped the light transport matrix as input such that the CNN can take advantage of spatial correlations between sensors. As a result, the proposed CNN outperforms support vector regression (SVR), K -nearest neighbor (KNN) regression and the model-based algorithm in localization of human occupants. Also, experiments with transfer learning demonstrated that a small training set (≈ 400 samples) is enough for the CNN to achieve good performance.

However, there is a trade-off between localization accuracy and ease of implementation. The CNN-based approach performs much better in realistic scenarios, since the model learns the real-world non-idealities (e.g., 3D shapes of human occupants, furniture, indirect light) from the training data. But a good training dataset can be expensive to collect in a real testbed, which is a large amount of effort when deploying the system into a new room. By contrast, the model-based approach requires strict modeling assumptions about the room, light, floor and object, which are not always satisfied in reality, but if we know the light source locations (e.g., *via* the CAD blueprint of the room) and have a device that can measure the sensor locations (e.g., a calibrated camera where sensors can be detected in the captured image), then it is much easier to deploy the system into a new room than using the CNN-based approach. Therefore, we need choose the method that best fits the usage scenarios and requirements for accuracy.

5.2 Future directions

This dissertation is a first step towards privacy-preserving indoor localization *via* active scene illumination, which mainly focuses on algorithm development and experimental validation. In addition to these, the following directions could be of potential interest to future researchers.

In our testbed, we used 12 light sources and 12 sensors and achieved good accuracy. However, experimental results in Fig. 4.8 suggest that we could remove a few sensors and still maintain good performance. Therefore, one interesting direction could be finding the minimum number of sources and sensors needed to achieve a certain level of accuracy using theoretical analysis. One could try to derive theoretical bounds for localization error or reconstruction error of $\Delta\alpha$, which is related to the number and locations of sources and sensors.

Another direction could be exploring the type of light sources or sensors used. Currently, our LEDs and single-pixel sensors both work in the visible light spectrum. These can be replaced with infrared light sources and sensors to make the flicker invisible to human eyes. One could also consider infrared light sources that generate structured light and infrared cameras that capture the pattern. In this way, we could reconstruct the scene in 3D and localize multiple objects more accurately. Besides localization, other indoor activity analysis tasks necessary for future smart room applications, including action recognition and pose estimation, could be explored.

Appendix A

Closed-form Solution to Ridge Regression Problem

The minimization problem (3.14) can be re-written as:

$$\begin{aligned}
\Delta\boldsymbol{\alpha}_0^* &= \arg \min_{\Delta\boldsymbol{\alpha}} \left[\|\Delta\mathbf{A} - \delta^2 C \Delta\boldsymbol{\alpha}\|_{l_2}^2 + \sigma \delta^2 \|\Delta\boldsymbol{\alpha}\|_{l_2}^2 \right] \\
&= \arg \min_{\Delta\boldsymbol{\alpha}} \left[\Delta\mathbf{A}^T \Delta\mathbf{A} - 2\delta^2 \Delta\mathbf{A}^T C \Delta\boldsymbol{\alpha} + \delta^4 \Delta\boldsymbol{\alpha}^T C^T C \Delta\boldsymbol{\alpha} + \sigma \delta^2 \Delta\boldsymbol{\alpha}^T \Delta\boldsymbol{\alpha} \right] \quad (\text{A.1}) \\
&= \arg \min_{\Delta\boldsymbol{\alpha}} \left[\Delta\boldsymbol{\alpha}^T (\delta^2 C^T C + \sigma I) \Delta\boldsymbol{\alpha} - 2\Delta\mathbf{A}^T C \Delta\boldsymbol{\alpha} \right].
\end{aligned}$$

Let $g(\Delta\boldsymbol{\alpha}) = \Delta\boldsymbol{\alpha}^T (\delta^2 C^T C + \sigma I) \Delta\boldsymbol{\alpha} - 2\Delta\mathbf{A}^T C \Delta\boldsymbol{\alpha}$. The function $g(\Delta\boldsymbol{\alpha})$ is a quadratic function of $\Delta\boldsymbol{\alpha}$ and the matrix $\delta^2 C^T C + \sigma I$ is positive definite (we assume $\delta, \sigma > 0$). The optimal solution is obtained by setting its gradient to zero:

$$\begin{aligned}
\nabla g(\Delta\boldsymbol{\alpha}) &= 2(\delta^2 C^T C + \sigma I) \Delta\boldsymbol{\alpha} - 2C^T \Delta\mathbf{A} = 0 \\
\Rightarrow \Delta\boldsymbol{\alpha}_0^* &= (\delta^2 C^T C + \sigma I)^{-1} C^T \Delta\mathbf{A}.
\end{aligned} \quad (\text{A.2})$$

For problem (3.16), we define vector $\Delta\boldsymbol{\alpha}'$ as a sub-vector of $\Delta\boldsymbol{\alpha}$ containing only $\Delta\alpha(x, y)$ values where $(x, y) \in \mathcal{Q}$, and C' as a sub-matrix of C containing only the columns corresponding to floor grid points inside \mathcal{Q} . Similarly, the optimal $\Delta\boldsymbol{\alpha}'^*$ can also be calculated in closed form:

$$\Delta\boldsymbol{\alpha}'^* = (\delta^2 C'^T C' + \sigma I)^{-1} C'^T \Delta\mathbf{A}. \quad (\text{A.3})$$

The optimal $\Delta\boldsymbol{\alpha}^*$ is then obtained by padding zeros into $\Delta\boldsymbol{\alpha}'^*$ that correspond to points $(x, y) \notin \mathcal{Q}$.
