# Analysis of abstract and concrete word processing in persons with aphasia and age-matched neurologically healthy adults using fMRI

Chaleece Sandberg and Swathi Kiran

Speech, Language, and Hearing Sciences, Sargent College of Health and Rehabilitation Sciences, Boston University, Boston, MA, USA

The concreteness effect occurs in both normal and language-disordered populations. Research suggests that abstract and concrete concepts elicit differing neural activation patterns in healthy young adults, but this is undocumented in persons with aphasia (PWA). Three PWA and three age-matched controls were scanned using fMRI while processing abstract and concrete words. Consistent with current theories of abstract and concrete word processing, abstract words elicited activation in verbal areas, whereas concrete words additionally activated multimodal association areas. PWA show greater differences in neural activation than age-matched controls between abstract and concrete words, possibly due to an exaggerated concreteness effect.

**Keywords:** Aphasia; Concreteness effect; fMRI; Semantic processing; Localization of function.

The exploration of language processing in persons with aphasia (hereafter PWA) using fMRI is highly informative for clinical aphasia research in particular and cognitive neuroscience in general. However, since acquired aphasia results from damage to neural tissue and is by definition a deficit in language processing, using fMRI to test theories of language processing in this population becomes highly reliant on task performance. Incorrect responses in the scanner have been shown to elicit different activation patterns than correct responses (e.g., Fridriksson, Baker, & Moser, 2009; Postman-Caucheteux et al., 2010), which can be useful for comparing posttreatment to pretreatment activations, but are confounding when localizing specific language processes in PWA. This is especially important when the goal is to tease apart very fine distinctions that are easily found in neurologically healthy cohorts, such as

the difference in activations for processing canonical versus noncanonical sentences (Wartenburger et al., 2004) and for processing sentences with object-relative clauses versus those with subject-relative clauses while varying plausibility (Caplan, Stanczak, & Waters, 2008). Such distinctions are revealed behaviorally as differences in reaction time in healthy participants, but as differences in both reaction time and accuracy in PWA. These psycholinguistic distinctions do not necessarily surface as differences in activations for participants with aphasia (e.g., Thompson, den Ouden, Bonakdarpour, Garibaldi, & Parrish, 2010), but this may be due to poor performance. In other words, the inability to perform a task may overshadow differences in activation. Therefore, in neuroimaging studies of language processing in PWA, it is important to carefully construct the experimental paradigm such that the participants

(a) exhibit a behavioral difference in the contrasts of interest and (b) are able to perform the task consistently with reasonable accuracy (Price, Crinion, & Friston, 2006).

One contrast that is informative in exploring semantic processing in PWA is the comparison between abstract and concrete word processing. The term “concreteness effect” is used to describe the difference in performance on lexical semantic processing tasks between abstract (e.g., *justice*) and concrete (e.g., *table*) words. Neurologically healthy individuals exhibit faster reaction times and more accurate responses for concrete versus abstract words during lexical decision, word recognition, recall, and sentence comprehension tasks (see Paivio, 1991 for a review). This effect is not only present, but more pronounced in PWA (Barry & Gerhand, 2003; Berndt, Haendiges, Burton, & Mitchum, 2002; Kiran, Sandberg, & Abbott, 2009; Newton & Barry, 1997). Some studies report a reverse effect, where abstract words are associated with faster reaction times and greater accuracy than concrete words in persons with semantic dementia (SD) or encephalitis (Bonner et al., 2009; Cipolotti & Warrington, 1995; Sirigu, Duhamel, & Poncet, 1991). However, note that Jefferies, Patterson, Jones, and Lambon Ralph (2009) found that the reverse concreteness effect appears to be the exception in SD rather than the rule. Regardless, there appears to be a double dissociation which provides evidence of differing neural substrates for the processing of abstract versus concrete words.

A handful of neuroimaging studies have examined the neural correlates for abstract and concrete word processing in healthy adults, but no clear consensus emerged until meta-analyses of these studies were performed (Binder, Desai, Graves, & Conant, 2009; Wang, Conder, Blitzer, & Shinkareva, 2010). Binder and colleagues (2009) examined 120 functional neuroimaging studies in order to identify specific brain regions that contribute to the semantic aspects of word retrieval. A subset of 17 studies in their analysis focused on the processing of “verbal” (abstract) and “perceptual” (concrete) concepts. Using the activation likelihood estimation (ALE) technique, they found stronger activation for concrete concepts in bilateral angular gyrus, which may play a role in supramodal integration; in left mid-fusiform gyrus, which may play a role in retrieving knowledge of visual attributes; in left dorsomedial prefrontal cortex, which may direct retrieval of semantic information; and in left posterior cingulate cortex, which may act as an interface

between episodic memory and semantic retrieval. Stronger activation for abstract concepts was found in left inferior frontal gyrus, which may mediate task efficiency in addition to phonological processing and working memory; and in left anterior superior temporal sulcus, whose proximity to left superior temporal gyrus suggests a verbal rather than perceptual role in semantic processing.

Wang and colleagues (2010) examined 19 functional neuroimaging studies of abstract and concrete concept processing, only 10 of which overlapped with the Binder et al. (2009) study. Using the multilevel kernel density analysis (MKDA) technique, they found similar results as Binder et al. (2009); namely, that abstract words activated left hemisphere language areas including inferior frontal, superior temporal, and middle temporal gyri, whereas concrete words activated areas related to mental image generation including left precuneus, posterior cingulate, fusiform, and parahippocampal gyri. The results of these meta-analyses are in line with the dual-coding theory, which posits that abstract words are processed in a verbal network, whereas concrete words are processed in a network that bridges language and multimodal processing (see Paivio, 1991 for a review).

The study of abstract and concrete word processing in PWA to date has not utilized fMRI, but has relied on comparing behavior with aphasia characteristics (in some cases including lesion characteristics) on a case-by-case basis (Barry & Gerhand, 2003; Berndt et al., 2002; Kiran et al., 2009; Newton & Barry, 1997; Tyler, Moss, & Jennings, 1995). Though informative, these types of studies cannot capture the subtle neuroanatomical differences in abstract and concrete word processing in aphasia; they can only suggest which areas, when damaged, cause deficits. One important reason to study abstract and concrete word processing not only psycholinguistically but also neurolinguistically in PWA is that this distinction has clinical relevance. Natural conversation requires the frequent use of abstract words and concepts. In aphasia, abstract word use is lessened relative to concrete word use—as mentioned previously—contributing to less natural, albeit functional conversation. Furthermore, a recent study by Kiran et al. (2009) showed that training abstract words results in improvement of those words as well as generalization to untrained target concrete words in the same context-category; however, training concrete words results in improvement of only those trained words. The authors suggest that the differential processing

of abstract and concrete words contributes to the differences in generalization, but the neurophysiological support for this explanation is incomplete.

Therefore, the present study examined the processing of abstract versus concrete nouns in PWA and age-matched neurologically healthy older adults (NHOAs) in order to shed more light on the underlying neural mechanisms for the concreteness effect. As mentioned previously, the concreteness effect is not only present, but more pronounced in PWA. If indeed abstract nouns are processed in a verbal-only network located in the left hemisphere and concrete nouns are processed in a network that is both verbal and multimodal sensory, then one would expect damage to the left hemisphere language areas to affect the processing of abstract words more than concrete words. Although this is most often what is seen behaviorally in PWA, the neural mechanisms for this behavioral phenomenon have not yet been explored, let alone confirmed.

The advantage of using abstract and concrete words to explore semantic processing in PWA is twofold. First, abstract and concrete words both elicit semantic processing in general, but according to the dual-coding theory, concrete words additionally elicit perceptual processing. This additional operation should require activation in perceptual areas, and in fact, this is what is seen in studies of healthy young adults. As suggested by Caplan (2009), in a model where two processes occur in parallel, the comparison between the two can inform the localization of function when one requires a unique operation. Therefore, abstract and concrete words provide a tight comparison with which to explore the subtleties of semantic processing. Second, PWA exhibit an exaggerated concreteness effect, suggesting that lesion characteristics may influence the neural correlates of abstract and concrete word processing.

In order to shed more light on the underlying neural mechanisms for the concreteness effect, we examined the neural activation patterns for abstract and concrete word processing of three PWA with varying degrees of lesion during two tasks with varying depth of semantic processing—word judgment and synonym judgment—and compared their data with three age-matched controls. We hypothesize that (a) similar to previous work, abstract and concrete words will produce differing patterns of activation such that abstract words are processed in a verbal network and concrete words additionally recruit multimodal association

areas and (b) PWA will show somewhat different activation patterns than their NHOA counterparts due to lesion characteristics. For example, PWA with very large lesions encompassing much of left hemisphere language areas may reorganize language function to right hemisphere language homologues (Sebastian & Kiran, 2011; Sebastian, Kiran, & Sandberg, 2012; Turkeltaub, Messing, Norise, & Hamilton, 2011).

## METHODS

### Participants

Three (one female) PWA subsequent to left middle cerebral artery cerebrovascular accident and three (two females) NHOAs participated in the experiment. PWA ranged in age from 55 to 59 years (mean = 57.19) and were in the chronic stage of recovery (23–76 months post-onset) (see Table 3 for details). NHOAs ranged in age from 56 to 67 years (mean = 59.7). All participants were right-handed, monolingual English speakers. Handedness was confirmed with the Edinburgh Inventory (Oldfield, 1971). A medical history and demographic questionnaire was used to rule out concomitant neurological disease, head trauma, psychiatric disorders, or developmental speech, language, or learning disabilities. Aided or unaided visual and hearing acuity was determined to be within normal limits. All participants obtained at least a high school education and gave informed consent according to the Human Subjects Protocol for Boston University.

PWA were given a battery of standardized language tests, including the *Western Aphasia Battery* (WAB; Kertesz, 1982) to establish the type and severity of aphasia, the *Boston Naming Test* (BNT; Goodglass, Kaplan, & Weintraub, 1983) to determine confrontation naming ability, the *Psycholinguistic Assessment of Language Processing in Aphasia* (PALPA; Kay, Lesser, & Coltheart, 1992) to determine specific deficits of access to the semantic system, the *Pyramids and Palm Trees* (PAPT; Howard & Patterson, 1992) to determine overall soundness of the semantic system, and the *Cognitive Linguistic Quick Test* (CLQT; Helm-Estabrooks, 2001) to determine the relative contribution of cognitive deficits such as attention and memory to language dysfunction (see Table 1 for details).

NHOAs completed the *Mini Mental State Exam* (MMSE; Folstein, Folstein, & McHugh, 1975)

<sup>a</sup>MCA = middle cerebral artery.

<sup>b</sup>DNT = did not test.

<sup>c</sup>WNL = within normal limits.

Note that most cases of differences in performance between high and low imageability reflect better performance for lexical items with high imageability, which are more concrete in nature.

and the *Boston Naming Test Short Form* (BNT; Goodglass et al., 1983) to rule out cognitive and semantic deficits. Average scores for these tests were 97% for the MMSE and 100% for the BNT.

### Tasks and stimuli

Two tasks were used to elicit specific semantic processing for abstract and concrete words: word judgment (WJ) and synonym judgment (SJ). In both tasks, participants made a semantic judgment and responded with a button press using the left hand. The left hand was used to equate the task between populations, since patients with aphasia are often hemiplegic on the right side. The two tasks were designed to elicit semantic processing at two different levels. The WJ task is a more metalinguistic task that requires only cursory semantic processing, whereas the SJ task requires access to meaning and is therefore a deeper semantic

task. All participants were allowed to practice both tasks until they felt comfortable performing each task.

In the WJ task, participants decided whether a word was abstract or concrete. The control condition for this task was deciding whether letter strings were composed of vowels or consonants. The words *abstract/concrete* for noun stimuli and *vowel/consonant* for letter stimuli appeared at the bottom of each screen in order to minimize possible confounding effects of participants not remembering which button to push.

The 50 abstract and 50 concrete words used for the WJ task, as well as their ratings for concreteness, imageability, and frequency were obtained from the Medical Research Council psycholinguistic database ([www.psy.uwa.edu.au/mrcdatabase/uwa\\_mrc.htm](http://www.psy.uwa.edu.au/mrcdatabase/uwa_mrc.htm); Frances & Kucera, 1983; Gilhooly & Logie, 1980; Toglia & Battig, 1978). Abstract and concrete words were chosen so that they were as far apart on the

concreteness and imageability spectrums as possible to ensure distinct behavioral and neurophysiological processing between word types. Therefore, abstract words had significantly lower concreteness ( $F(1, 98) = 2161.20, p < .01$ ) and imageability ( $F(1, 98) = 494.70, p < .01$ ) than concrete words. Abstract and concrete words were matched on frequency ( $F(1, 84) = 2.27, p = .13$ ). The length of each letter string was matched to the letter length of each concrete and abstract word.

In the SJ task, participants decided whether or not paired abstract and paired concrete words were similar in meaning. The control condition was to decide whether or not paired nonwords were the same.

The 50 abstract and 50 concrete words used in the SJ task were taken from a previous treatment study in our lab (Kiran et al., 2009) and from a subset of the PALPA (Kay et al., 1992). Psycholinguistic information for these words was also obtained from the MRC database ([www.psy.uwa.edu.au/mrcdatabase/uwa\\_mrc.htm](http://www.psy.uwa.edu.au/mrcdatabase/uwa_mrc.htm); Frances & Kucera, 1983; Gilhooly & Logie, 1980; Toglia & Battig, 1978). Again, abstract words had significantly lower concreteness ( $F(1, 65) = 846.43, p < .01$ ) and imageability ( $F(1, 68) = 456.34, p < .01$ ) than concrete words, but abstract and concrete words were matched on frequency ( $F(1, 54) = .27, p = .61$ ).

The 50 nonwords used in the SJ task were obtained from the ARC nonword database (Rastle, Harrington, & Coltheart, 2002) and were matched in letter length with the abstract and concrete words. Additionally, nonwords with no phonological or orthographic neighbors were chosen so that unintentional processing of real words did not occur due to similarities between nonwords and real words.

### Experimental design

For both tasks, an event-related design was implemented using E-Prime software (Psychology Software Tools, Inc., Sharpsburg, PA, USA). Each event stimulus lasted 4 seconds and presentation was randomized within tasks. During each inter-stimulus interval (ISI), which randomly lasted 2, 3, or 4 seconds, a small cross centered on the screen was presented to maintain the subject's visual attention. The WJ task consisted of three runs, lasting a total of 17.45 minutes. The SJ task consisted of four runs, lasting a total of 23.27 minutes.

### Data collection

Magnetic resonance images were acquired at the Boston University Center for Biomedical Imaging from a 3T Philips MRI scanner. High-resolution T1 images were acquired with the following parameters: 140 sagittal slices, 1 mm<sup>3</sup> voxels, 240 × 240 matrix, field of view (FOV) = 240 mm, flip angle = 8, fold-over direction = anterior-posterior (AP), repetition time (TR) = 8.2 ms, and echo time (TE) = 3.8 ms. Blood-oxygen-level-dependent (BOLD) sensitive functional images were collected using the following parameters: 31 axial slices (3 mm thick, 0.3 interslice gap), 3 mm<sup>3</sup> voxels, FOV = 240, flip angle = 90, fold-over direction = AP, TR = 2000 ms, and TE = 35 ms. The visual stimuli were presented on a screen behind the scanner, which projected to a mirror fitted to the head coil. Padding was used to minimize head motion and corrective optical lenses were used when necessary to correct visual acuity. After bore entry, the magnet was shimmed to achieve maximum homogeneity.

### Data analysis

SPM8 software (Wellcome Trust Centre for Neuroimaging, University College London, UK) was used to analyze the fMRI data. Preprocessing was performed to correct slice time differences, remove movement and baseline function artifacts, align the structural and functional images to each other, and normalize both structural and functional images to the MNI (Montreal Neurological Institute) template. Baseline functions were filtered out with a high-pass filter of 128 s cut-off period; motion artifacts were corrected using the ArtRepair toolbox for SPM8 (Mazaika, Hoefft, Glover, & Reiss, 2009). In addition to these basic steps, the preprocessing of PWA data required that lesion masks be drawn using MRIcron software (<http://www.cabiatl.com/mricro/>) and used during normalization to minimize deformities during warping (Brett, Leff, Rorden, & Ashburner, 2001). MRIcron was also then used to calculate the lesion volume for each patient. Additionally, patient data were not smoothed because (a) this data is not intended to be analyzed in a group analysis—which is the primary reason for smoothing data—and (b) smoothing may mask small but important activations in patient data (see Meinzer et al., 2012, for a discussion regarding smoothing in patient populations).

After preprocessing, statistical analyses were performed at the individual level with a general linear model (GLM) convolved with a canonical hemodynamic response function (HRF) with a temporal derivative. Only correct responses were analyzed. The contrasts of interest were abstract words > control items, concrete words > control items, abstract words > concrete words, and concrete words > abstract words.

## RESULTS

### Behavioral results

Analyses were performed on both accuracy and reaction time (RT) data (see Table 2). Nonparametric Kruskal–Wallis and Mann–Whitney *U*-tests were used due to small sample sizes. For the Kruskal–Wallis tests, there were three levels of the factor *conditions*: abstract, concrete, and control. Overall, PWA and NHOAs did not differ significantly in reaction time on either task ( $p = .51$  for both), nor in accuracy on the WJ task ( $p = .82$ ), but during SJ, NHOAs were more accurate than PWA ( $U = 3.86, p = .05$ ). This indicates that the SJ task was more difficult for PWA than for NHOAs. For specific effects of condition, PWA data were analyzed separately from NHOA data.

### Participants with aphasia

*Accuracy.* The Kruskal–Wallis test revealed a significant effect of condition on accuracy for

both tasks (SJ:  $H(2) = 32.20, p < .001$ ; WJ:  $H(2) = 46.59, p < .001$ ). Post-hoc Mann–Whitney *U*-tests revealed that PWA were less accurate for abstract than concrete words (SJ:  $U = 8.66, p < .01$ ; WJ:  $U = 23.42, p < .001$ ). For the SJ task, PWA were less accurate for concrete words than non-words ( $U = 4.76, p < .05$ ), but in the WJ task, there was no difference in accuracy between concrete words and letter strings ( $U = 2.02, p = .16$ ). These results confirm the existence of the concreteness effect in PWA.

*Reaction time.* The Kruskal–Wallis test showed a significant effect of condition on RT for both tasks (SJ:  $H(2) = 101.76, p < .001$ ; WJ:  $H(2) = 38.76, p < .001$ ). Post-hoc Mann–Whitney *U*-tests revealed that PWA were faster for concrete than abstract words (SJ:  $U = 11.64, p = .001$ ; WJ:  $U = 22.66, p < .001$ ). For the SJ task, PWA were faster for nonwords than concrete words ( $U = 55.28, p < .001$ ), but in the WJ task, there was no difference in reaction time between concrete words and letter strings ( $U = 1.96, p = .16$ ). These results again confirm the concreteness effect in PWA.

### Neurologically healthy older adults

*Accuracy.* The Kruskal–Wallis test revealed a significant effect of condition on accuracy for SJ ( $H(2) = 17.62, p < .001$ ), but not for WJ ( $H(2) = 4.00, p = .14$ ). Post-hoc Mann–Whitney *U*-tests for the SJ task revealed that NHOAs were less accurate for abstract words than concrete words ( $U = 6.11,$

<sup>a</sup>NHOAs = Neurologically healthy older adults.

<sup>b</sup>PWA = Persons with aphasia.

Reaction time is given in milliseconds; Standard deviations shown in parentheses.

$p = .01$ ), but there was no difference in accuracy between concrete words and nonwords ( $U = .51$ ,  $p = .48$ ). These results confirm the existence of the concreteness effect in NHOAs for SJ but not WJ.

**Reaction time.** The Kruskal–Wallis test showed a significant effect of condition on RT for both tasks (SJ:  $H(2) = 9.23$ ,  $p = .01$ ; WJ:  $H(2) = 20.50$ ,  $p < .001$ ). Post-hoc Mann–Whitney  $U$ -tests revealed differing patterns for each task. For SJ, NHOAs exhibited longer RTs for abstract words than concrete words ( $U = 4.79$ ,  $p < .05$ ), but there was no significant difference in RT between concrete words and nonwords ( $U = .33$ ,  $p = .57$ ). For WJ, NHOAs exhibited longer RTs for letter strings than for both abstract words ( $U = 19.28$ ,  $p < .001$ ) and concrete words ( $U = 11.46$ ,  $p = .001$ ), but there was no significant difference in RT between abstract and concrete words ( $U = .08$ ,  $p = .78$ ). These results

again confirm the concreteness effect in NHOAs, depending on the task.

## Neuroimaging results

Data from each participant were analyzed at the individual level, corrected with an FDR of  $p < .05$ . FDR was used rather than FWE because the data were not smoothed and the FWE procedure requires the data to be smoothed.

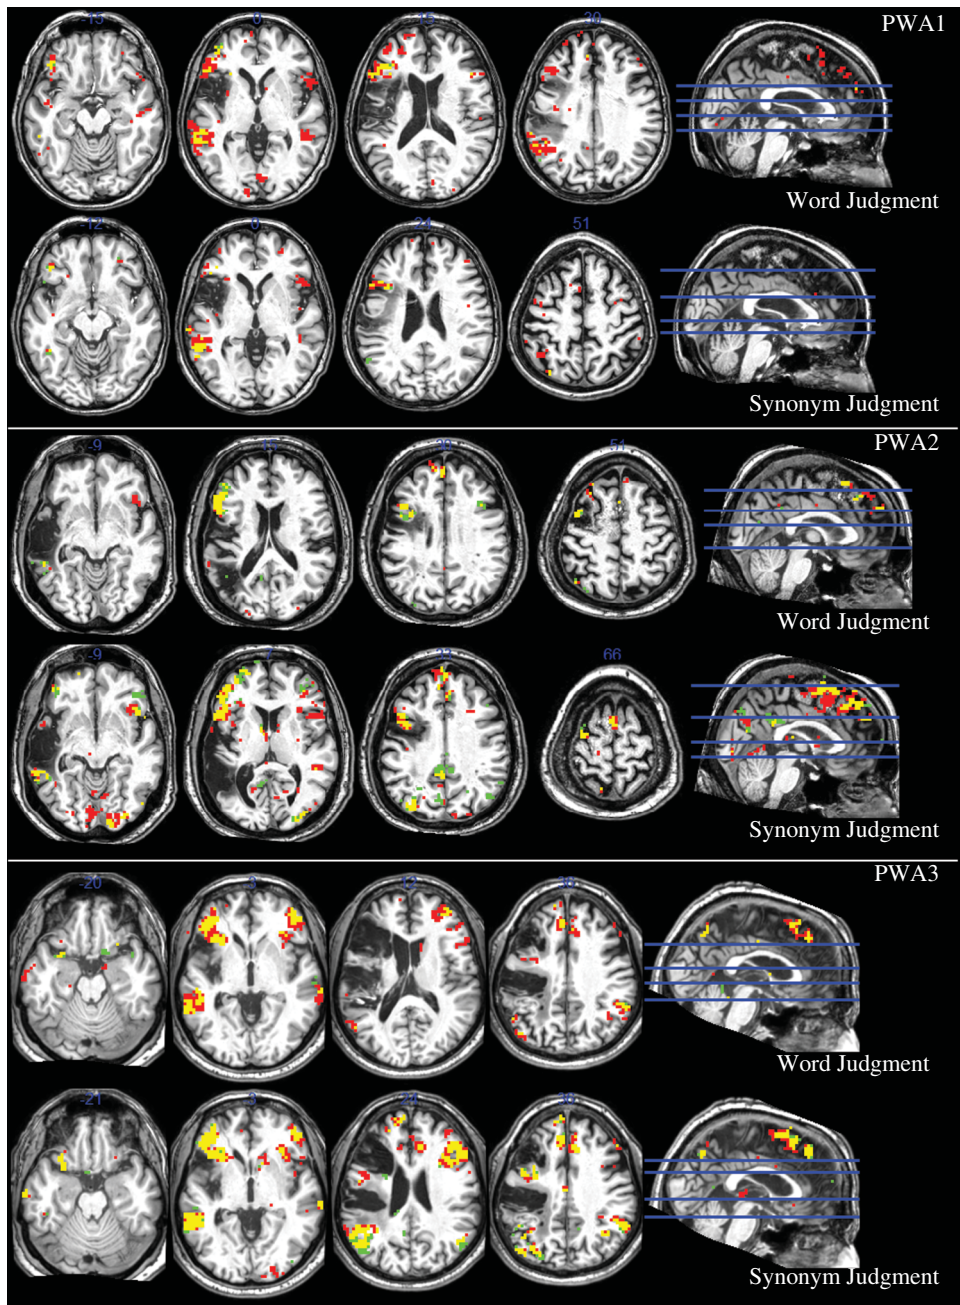

### Participants with aphasia

Importantly, all PWA showed patterns of activation that showed certain consistencies (see Figures 1 and 2). First, all PWA showed activation in some portion of left IFG, regardless of task or word type. Second, all PWA exhibited bilateral activation, again, regardless of task or word type. Third,

**Figure 1.** Activations for persons with aphasia (PWA). Activation shown at FDR of  $p < .05$  for tight contrasts abstract > concrete (red) and concrete > abstract (blue). [To view this figure in color, please visit the online version of this Journal.]

**Figure 2.** Activations for persons with aphasia (PWA). Activation shown at FDR of  $p < .05$  for contrasts abstract > control (red) and concrete > control (green). Yellow = overlap between contrasts. [To view this figure in color, please visit the online version of this Journal.]

all PWA showed greater activation for abstract than concrete words. PWA's specific neuroimaging results are described separately below.

*PWA1.* The first PWA was a 56-year-old female with a lesion encompassing about 85 cc of the left hemisphere including roughly 48% of left IFGtri

and 32% AG/SMG (see Table 3). During the word judgment task, for the abstract > concrete contrast, this participant activated left IFGorb, left IFGtri, and left MTG, as well as many additional areas, including right hemisphere homologues (see Table 4 and Figure 1). The concrete > abstract contrast did not result in any significant activation. The broader

**TABLE 3**  
Lesion information for participants with aphasia

	<i>PWA1</i>	<i>PWA2</i>	<i>PWA3</i>
<i>Lesion volume</i>	<i>85 cc</i>	<i>133 cc</i>	<i>228 cc</i>
Percentage of spared tissue by region of interest			
Left inferior frontal gyrus p. opercularis	7.63	23.79	1.15
Left inferior frontal gyrus p. orbitalis	85.50	87.43	70.08
Left inferior frontal gyrus p. triangularis	52.09	70.47	2.06
Left middle frontal gyrus	86.08	73.31	21.38
Left superior frontal gyrus	100.00	99.77	85.99
Left middle temporal gyrus	99.97	13.71	82.45
Left angular and supramarginal gyri	67.94	69.49	11.15

contrasts of abstract > control and concrete > control show much overlap between abstract and concrete word processing (see Table 4 and Figure 2) which aligns with the fact that the tight contrast of concrete > abstract was not significant.

During the synonym judgment task, *PWA1* did not show significant activation for either the abstract > concrete contrast or the concrete > abstract contrast. Again, the broader contrasts of abstract > control and concrete > control show much overlap between abstract and concrete word processing, but some subtle differences emerge, such as activation in left AG for the concrete > control contrast and left STG for the abstract > control contrast (see Table 4 and Figure 2).

*PWA2*. The second PWA was a 55-year-old male with a lesion encompassing about 133 cc of the left hemisphere including roughly 30% of IFGtri, 27% of MFG, 86% of MTG, and 31% of AG/SMG (see Table 3). During the word judgment task, this participant activated left MTG for the abstract > concrete contrast, as well as bilateral middle cingulate cortex (MCC) and precuneus, right MFG and MTG, and left SFG (see Table 5 and Figure 1). The concrete > abstract contrast was not significant. Like *PWA1*, the broader contrasts (abstract > control and concrete > control) reveal much overlap between abstract and concrete word processing (see Table 5 and Figure 2 for details).

During the synonym judgment task, *PWA2* did not show significant activation for either the abstract > concrete contrast or the concrete > abstract contrast. The broader contrasts of abstract

> control and concrete > control again showed similar patterns of activation (see Table 5 and Figure 2 for details), but notable differences included bilateral anterior cingulate cortex (ACC) and left insula for the abstract > control contrast and bilateral IFGop for the concrete > control contrast. Additional areas of activation for these contrasts are listed in Table 5.

*PWA3*. The third participant was a 59-year-old male with a lesion encompassing about 228 cc of the left hemisphere including roughly 30% of IFGorb, 98% of IFGtri, 79% of MFG, and 89% of AG/SMG (see Table 3). During the word judgment task, he showed significant activation in left IFGorb and MTG for the abstract > concrete contrast and for the concrete > abstract contrast, left dorsomedial prefrontal cortex (DMPFC), AG, precuneus, and parahippocampal gyrus were significantly active. Additional areas that were active for these contrasts are listed in Table 6 and shown in Figure 1. The broader contrasts of abstract > control and concrete > control showed some similar areas of activation, but again, notable differences surfaced, including left STG for the abstract > control contrast and left fusiform gyrus for the concrete > control contrast. Additional areas of activation for these contrasts are listed in Table 6 and shown in Figure 2.

During the synonym judgment task, *PWA3* showed activation in left IFGorb, IFGtri, and MTG for the abstract > concrete contrast and in left inferior parietal cortex, PCC, and precuneus for the concrete > abstract contrast, in line with the existing literature. Additional areas for these contrasts are listed in Table 6 and shown in Figure 1. Again, the broader contrasts of abstract > control and concrete > control showed some activation similarities, but again some differences stand out, such as significant activation in left AG for the concrete > control contrast (see Table 6 and Figure 2 for details).

### **Neurologically healthy older adults**

As in PWA, NHOAs showed certain consistencies in their patterns of activation (see Figure 3). First, all NHOAs showed activation in left IFG. Unlike in PWA, this activation appeared to be mediated by task and word type. Second, NHOAs showed fewer regions of activation overall than PWA, constrained to mainly left hemisphere language areas, but notable exceptions exist, including

Note: All activation significant at FDR  $p \leq .05$ .

**Figure 3.** Activations for neurologically healthy older adults (NHOAs). Activation shown at  $FDR p < .05$  for contrasts abstract > control (red) and concrete > control (green). Yellow = overlap between contrasts. [To view this figure in color, please visit the online version of this Journal.]

bilateral activations which appear to be mediated by task and word type. Third, all NHOAs showed greater activation for abstract than concrete words, which effect also appeared to be mediated by task. Each NHOA's specific neuroimaging results are described separately below.

*NHOA1.* The first participant was a 67-year-old female. During the word judgment task, this

participant did not show activation for the tight contrasts of abstract > concrete and concrete > abstract. The broader contrasts of abstract > control and concrete > control showed much overlap, but differences included activation in left superior medial gyrus for the abstract > control contrast and activation in left fusiform gyrus, PCC, and precuneus for the concrete > control contrast (see Table 7 and Figure 3 for details).

During the synonym judgment task, the abstract > concrete contrast showed activation in left IFG (p. orbitalis and opercularis) and MTG, as well as additional areas listed in Table 7, but the concrete > abstract contrast did not reveal any significant areas of activation. The broader contrasts of abstract > control and concrete > control showed overlap, but notable differences included activation in right IFGorb and left STG for the abstract > control contrast and activation in left ITG for the concrete > control contrast (see Table 7 for details).

*NHOA2.* The second participant was a 56-year-old male. During the word judgment task, this participant did not show activation for the tight contrasts of abstract > concrete and concrete > abstract. The broader contrasts of abstract > control and concrete > control showed similar activation patterns, but the abstract > control contrast additionally activated left superior medial gyrus, SFG, AG, and PCC (see Table 8 and Figure 3 for details).

Like the word judgment task, the synonym judgment task showed no significant activation for the tight contrasts of abstract > concrete and concrete > abstract. Additionally, there was no significant activation for the broad contrast of concrete > control. However, the abstract > control contrast showed activation in left IFG (p. orbitalis and triangularis) and MTG (see Table 8 and Figure 3 for details).

*NHOA3.* The third participant was a 56-year-old female. During the word judgment task, this participant showed activation in left superior parietal lobule for the tight contrast of abstract > concrete, but did not show activation for the tight contrast of concrete > abstract. The broader contrast of abstract > control approached significance in left IFG and MTG, and the concrete > control contrast showed activation in left MTG (see Table 9 and Figure 3 for details).

During the synonym judgment task, the abstract > concrete contrast showed activation in areas including left IFGtri, STG, and MTG, but the concrete > abstract contrast did not reveal any significant areas of activation (see Table 9). The broader contrast of abstract > control showed much more activation than the concrete > control contrast, with the only overlap occurring in left MTG (see Table 9 and Figure 3 for details).

## DISCUSSION

We examined the neural activation patterns for abstract and concrete word processing of three PWA with varying degrees of lesion during two tasks with varying depth of semantic processing and compared their data with three age-matched controls in order to shed more light on the concreteness effect seen in both neurologically intact adults and PWA. As mentioned in the introduction, the abstract-concrete distinction provides a unique opportunity for studying semantic processing in PWA because abstract and concrete words have been shown to elicit differing patterns of activation in neurologically intact adults (e.g., Binder et al., 2009; Wang et al., 2010) and can be differentially impaired due to brain damage.

Both NHOAs and PWA showed differing patterns of activation for abstract and concrete word processing, confirming our first hypothesis. The direct contrast of abstract > concrete was significant in two of the three NHOAs and in all three PWA, and the direct contrast of concrete > abstract was significant in one PWA, but none of the NHOAs. It is interesting to note that the NHOAs did not show as robust differences between abstract and concrete word processing as PWA. This lack of robustness and agreement among NHOAs is not altogether surprising, since there were only three participants. The studies leading up to the Binder et al. (2009) and Wang et al. (2010) meta-analyses were not in agreement until all their data were pooled together. That being said, it is somewhat surprising that the PWA show such robust neural activation differences. It is possible that the exaggerated concreteness effect seen in patients behaviorally translates to more robust differences in neural activation between abstract and concrete word processing.

When the direct contrasts of abstract > concrete and concrete > abstract were significant, areas that were shown to be active were in line with previous work and with the dual-coding theory, as can be seen in Table 10 and Figure 1. Interestingly, additional areas of activation for these contrasts were also noted for both NHOAs and PWA, but to a much greater extent for the PWA (see Tables 4–9). These additional areas that were not also observed in the Binder et al. (2009) and Wang et al. (2010) meta-analyses may have been recruited due to increased effort.

Only areas matching with previous meta-analyses shown. For current study, each X represents activation for one participant. See text for abbreviations of anatomical areas.

Furthermore, there appears to be an effect of task. For PWA, there are more areas active for both abstract > concrete and concrete > abstract contrasts in the WJ task than in the SJ task. For NHOAs, this trend is reversed. The WJ task may require deeper semantic processing from the PWA than the NHOAs, resulting in greater differences between abstract and concrete word processing for PWA in this task. The SJ task, which is meant to require deeper semantic processing than the WJ task, may be the depth of semantic processing necessary to show the maximum differences in abstract and concrete word processing for NHOAs, but for PWA, the increased difficulty for this task may overshadow inherent differences between abstract and concrete word processing. These speculations are tentative and would need to be confirmed with more subjects.

It is also informative to qualitatively compare the activation patterns of abstract and concrete words when each has had the control condition removed. PWA activated areas consistent with their age-matched counterparts as well as areas consistent with previous work. Specifically, regardless of task, all three PWA activated left IFG, STG, and MTG for abstract word processing (see Figure 2 and Tables 4–6), which is consistent with both the existing literature and all three NHOAs (see Figure 3 and Tables 7–9). For concrete word processing, again regardless of task, all three PWA

activated left AG, PCC, and portions of DMPFC (see Figure 2 and Tables 4–6), in line with the existing literature and at least one NHOA (see Figure 3 and Table 7). Thus, the qualitative comparison of abstract > control and concrete > control contrasts for both the WJ task and the SJ task confirms the results of the abstract > concrete and concrete > abstract contrasts and suggests that with more data, these tentative results are likely to become more robust.

Importantly, NHOAs and PWA show surprisingly similar patterns of activation for abstract and concrete words in this experiment. Most notably, both NHOAs and PWA activated left IFG (p. triangularis and orbitalis) and MTG for both abstract and concrete words. In fact, all three PWA activated all three of these areas, which is quite remarkable considering the fact that PWA2 is missing roughly 85% of left MTG and PWA3 is missing roughly 95% of IFGtri. This result reinforces the importance of left IFG and MTG for semantic processing in general (Lau, Phillips, & Poeppel, 2008; Vigneau et al., 2006).

The differences that surface appear to be influenced by cognitive demand, task, and lesion characteristics; therefore, our second hypothesis that differences between NHOAs and PWA would be due to lesion characteristics is supported and extended to task and cognitive demand. PWA in general, show increased activity in comparison to NHOAs.

This is in the face of similar task performance; in fact, for the WJ task, there was no statistically significant difference in behavioral performance between the two groups. In order to maintain this level of performance, PWA almost certainly require more cognitive effort due to their language deficit caused by damage to the left perisylvian region. This increased effort may be reflected in increased global activity.

Additionally, all three PWA showed perilesional activation. PWA1 showed activation in left IFGtri and AG, even though both areas were lesioned. PWA2's lesion was much larger than PWA1's, but he too showed activation in lesioned areas including left IFG, MFG, MTG, and AG areas for abstract and/or concrete words, depending on the task. When PWA2 did not show activation in left MTG and AG for abstract words as NHOAs did, the amount of damage in these areas could be to blame. Although PWA3's lesion was the largest, he also activated lesioned areas, including left IFGtri, MFG, and AG/SMG for abstract and/or concrete words, depending on the task. When these areas were active in NHOAs, but not PWA3, the right hemisphere homologue was often active (see Results for details).

These individual patterns of activation can be interpreted in the light of the amount of spared tissue in each region of interest and with respect to the existing literature examining the neural correlates of language recovery after stroke. For all three PWA, the activation in spared tissue surrounding the lesion in areas such as left IFG and MTG, suggest restoration of function (e.g., Fridriksson, Richardson, Fillmore, & Cai, 2012; Meinzer et al., 2008; Saur et al., 2006; Turkeltaub et al., 2011). Additionally, right hemisphere homologues were recruited for all three PWA, which may be indicative of a reorganization of language function or may represent supplementary—possibly nonessential—processing. For PWA3, who had the largest lesion and the most right hemisphere activation, RH activation may reflect compensation, but for the other PWAs, whose lesions were not as extensive and who had less right hemisphere activation than PWA3, this may simply reflect increased effort. Because of the small sample size, it is impossible to conduct meaningful statistics to determine the relationship between lesion characteristics and activation patterns; therefore, substantial conclusions regarding the relative contributions of perilesional and contralesional activations cannot be made at this time.

## CONCLUSIONS

The results of this study are in line with previous neuroimaging studies of abstract and concrete word processing showing that abstract words are processed in a mainly verbal network, whereas concrete words are processed in a mainly perceptual network (e.g., Binder et al., 2009; Wang et al., 2010). We found this to be true in PWA and their neurologically healthy age-matched counterparts. PWA and NHOAs exhibit remarkably similar activation patterns, although notable differences do exist. These differences are most likely due to lesion characteristics and help to inform the process of language recovery after stroke. Notably, PWA activated both spared tissue and right hemisphere homologues. Although this work is tentative due to the small sample size, these activations appear to be reorganization of function rather than maladaptive compensation, due to the relatively high performance of these participants.

Some limitations of this study are the small sample sizes and the similarity in aphasic profiles of the patients. Future work will incorporate more participants with greater variation in aphasia severity, with correlations between behavior and activation being conducted. Additionally, we plan to explore changes in abstract and concrete word processing as a function of a theoretically based treatment focused on abstract word training. As mentioned in the introduction, PWA show an exaggerated concreteness effect which has been successfully manipulated in treatment to boost its therapeutic effects (Kiran et al., 2009). Knowing where abstract and concrete words are normally processed and how that processing may shift due to aging and left-hemisphere stroke will aid in discovering why the concreteness effect is exaggerated in PWA and why training abstract words seems to be more beneficial than training concrete words. This study is a step forward in a continued effort to understand the mechanisms underlying word retrieval deficits in aphasia in order to adopt more effective treatment methods.
